Abstract

Existing research documents substantial disparities in life outcomes between same-sex and different-sex attracted individuals, typically disadvantaging same-sex attracted individuals. We analyse how parental background relates to adult children's earnings, health, fertility, and family formation by sexuality. To do so, we develop a new strategy to identify same-sex couples in population-wide administrative data using joint financial commitments from Denmark. Our approach mitigates limitations associated with non-representative surveys and cross-sectional data on sexuality. We find that disparities in outcomes persist across the parental income distribution; (dis)advantages for same-sex attracted individuals are only partially mediated by parental income. We explore parent-child dynamics as potential mechanisms, including proximity to parents. Results are robust to controlling for unobserved parental heterogeneity through sibling fixed effects, but vary across childhood regions and cohorts. Our findings suggest that intergenerational mobility depends not only on factors shared by siblings but also on innate individual characteristics, such as sexuality.

JEL classifications: D64, J10, J16 Keywords: sexuality, couples, intergenerational mobility

"I will never forget what it was like coming out and having nobody to look up toward. I remember the lack of hope – and our friends can't fulfil it... And the young gay people who are coming out... The only thing they have to look forward to is hope... Hope for a better world, hope for a better tomorrow, hope for a better place to come to if the pressures at home are too great."

Harvey Milk, 25 June 1978, four months before his assassination.

1 Introduction

Since Badgett's canonical work was published in 1995, economic, sociological, and demographic research has continued to document substantial gaps in outcomes between same-sex and different-sex attracted individuals. These gaps extend to labour market outcomes, fertility, and health, almost always disadvantaging same-sex attracted individuals through lower earnings, fertility, and worse mental health outcomes. The primary exceptions are higher education levels among same-sex attracted individuals and higher earnings of same-sex attracted women (Badgett, 1995, 2020; Klawitter, 2015; Mize, 2016). In recent years, the fight for equal opportunities for sexual minority individuals has occupied a prominent role in the public discourse, and yet, we remain far from understanding the underlying mechanisms by which those who choose partners of the same sex experience substantially different health and economic outcomes compared to the heterosexual majority. Understanding these mechanisms is vital not only for improving sexual minorities' life trajectories but also because such improvements generate positive aggregate economic effects (Badgett, 2020).

In this paper, we analyse the origins of the differences in outcomes between same-sex attracted and different-sex attracted individuals from the perspective of intergenerational mobility, identifying sexuality as a core dimension of mobility stratification, equal in importance to gender. We harness Danish population-wide administrative data and develop a new measure of sexuality based on newly released data on shared financial commitments in Denmark, which allows us to identify unmarried couples. With these new data, we observe same-sex and different-sex attracted individuals before and after relationship spells, linking them to parental (and sibling) information to explore how parental earnings relate to labour market, health, fertility, and household outcomes by sexuality. As such, we explore the underlying intergenerational patterns of the different life trajectories of same-sex and different-sex attracted individuals, focusing on where all life trajectories start: with the parents.

Whereas sexuality will often play an important role in the relationship between romantic partners, it may also affect the relationship between a person and their parents. Sexual minority individuals may experience different parent-child relationships, including less

closeness (Hank & Salzburger, 2015), earlier and more distant moves from home (Fischer & Kalmijn, 2021), parental non-acceptance (Mills-Koonce et al., 2018), and increased risk of youth homelessness (Dempsey et al., 2020). This suggests reduced or different parental support compared to different-sex attracted individuals. Additional evidence suggests that higher educational attainment and income are associated with more supportive attitudes towards same-sex attracted individuals (Slenders et al., 2014; La Roi & Mandemakers, 2018). Whether this means that sexual minority individuals benefit more or less from parental characteristics like high earnings – known to improve later-life outcomes (see e.g. Chetty et al., 2014, 2020) – remains unknown, making intergenerational mobility analysis crucial for understanding sexual minorities' potentially unique challenges throughout the lifecycle.

Observing sexuality in population-wide data is notoriously challenging, thus far, leaving it unclear how to best obtain valid information about sexuality at a large scale and in a longitudinal setting. Sexuality may refer to sexual identity, sexual desires, and/or sexual practises, and such information is generally unavailable in register-based, population-wide data. Therefore, researchers tend to use surveys to assess sexuality, often asking about sexual identity (straight, gay, bi, other, etc.). However, surveys often include only small samples of sexual minorities (compromising precision) and tend to allow for only relatively static analyses because individuals cannot be observed over an extended period, let alone across generations. Survey responses may also be affected by social desirability bias (with non-straight individuals withholding information on their sexuality). In addition, the usefulness of self-declared sexual orientation in survey responses has come into question, as an increasing number of individuals do not identify with traditional labels (e.g. gay, bi, and straight) or choose not to declare a sexual identity (Julian et al., 2024b).

The removal of legal barriers to the official recognition of same-sex relationships in several countries over the last three decades has made it possible to observe sexual minorities in marriage registers (e.g. Kolk & Andersson, 2020; Andersson et al., 2006). This approach has significantly expanded our knowledge of sexual minority demographics and economic outcomes, but it also comes with certain challenges. For example, the uptake of marriage is still much lower for same-sex couples (Carpenter, 2020; Compton & Kaufman, 2024), those same-sex couples who do get married are likely to be of higher socio-economic status (Manning & Payne, 2021), and more same-sex couples than different-sex couples cohabit without getting married (Manning et al., 2022). Statistical agencies and demographers therefore call for more inclusive practices when identifying sexual minorities, highlighting cohabitation

¹See e.g. an extensive discussion on limitations of current data sources in Badgett et al. (2024).

history as a way of tackling some of these recurrent issues (Julian et al., 2024a). However, for cohabitation to be a useful proxy for sexuality, we must distinguish housemates from cohabiting partners. In surveys, this can be done by asking respondents if they cohabit with a partner, and if so, the sex of that partner. However, surveys are often not available at the population level, and if they are, they only allow for a snapshot of cohabitation status (as is the case in census data). On the other hand, administrative data agencies often systematically misclassify same-sex couples as housemates or automatically assumes that cohabiting individuals of different sexes are partners (e.g. Statistics Denmark, 2024; Statistics Finland, 2024).

We largely overcome these limitations using newly released population-wide data on financial commitments (shared bank accounts, bank loans, mortgages, properties) from Statistics Denmark. We identify cohabiting couples by exploiting that almost all cohabiting couples in Denmark have at least one shared financial commitment; this is not the case for housemates. Using this strategy, we obtain population-wide data on cohabiting couples, including same-sex couples. We observe individuals before, during, and after each spell of cohabitation, allowing for a cohabitation-based measure of sexuality across all these states. We observe people over time, in all cohabitating relationships they form, enabling a dynamic sexuality measure, which means that we do not have to assume that sexuality is static or binary. In this paper, we focus primarily on individuals who have cohabited only with same-sex or different-sex partners. As we are the first to use these data on financial commitments to identify couples, we undertake a series of validation exercises to ensure that we correctly identify couples. Combined with Danish registers from 1980 onward, this enables comprehensive intergenerational analysis beyond the scope of small, cross-sectional datasets or community-generated datasets on sexual minorities.

Our primary contribution is the analyses of intergenerational mobility by sexuality, but our new population-wide cohabitation measure also offers interesting information on differences in mean outcomes between same-sex attracted and different-sex attracted individuals in the labour market, education, fertility, health, and more – all within the same geographical setting and within the same population. Interestingly, we find that same-sex and different-sex attracted adult children are equally represented across the parental income distribution, i.e., we find no evidence of economically meaningful selection by parental background. Despite this lack of selection by parental background, we find substantial differences between same-sex and different-sex attracted adult children across almost all outcomes. For example, we identify a mean earnings penalty for same-sex attracted men

and a mean premium for same-sex attracted women, the latter of which closes in younger cohorts. This corresponds to the findings of previous meta-analyses (Klawitter, 2015; Drydakis, 2022). We find this earnings penalty for same-sex attracted men, even though we also document higher levels of educational attainment among both same-sex attracted men and women (in line with e.g. Black et al., 2000).² We also show that same-sex attracted individuals have lower household income, more psychiatric hospital visits, and more mental health prescriptions when compared to the different-sex attracted majority. That these differences in means align with those of previous studies from diverse contexts not only confirm that such findings hold within a coherent setting, but this also lends further creditability to our new measure of sexuality. We further add to the understanding of these gaps by considering them from an intergenerational perspective.

To study intergenerational relationships and mobility, we follow the approach by Chetty et al. (2014, 2020), allowing us to compare child-parent intergenerational relationships for adult children who are or have been in relationship(s) with same-sex or different-sex partners. Chetty et al. (2014) popularised the use of rank-rank regressions to study intergenerational relationships between child and parent income, and, more recently, rank-rank regressions have also been used to compare levels of intergenerational mobility across demographic characteristics beyond sex, such as race (see e.g. Chetty et al., 2020) and parental migration status (see e.g. Abramitzky et al., 2021; Boustan et al., 2025). Typically, these demographic characteristics are assumed to be fixed within a given family. We contribute to this literature by examining differences in intergenerational mobility based on sexuality, a characteristic that often varies within families.

Like Chetty et al. (2014, 2020), we distinguish between gaps in absolute and relative mobility. In a rank-rank regression, absolute mobility gaps reflect differences in outcomes between same-sex attracted and different-sex attracted individuals at the intercept, i.e., for those with parents at the bottom of the income distribution.³ Relative mobility gaps reflect differences in slopes, i.e., the value with which the outcome of interest changes when parental income rank increases. In our setting, we can interpret differences in absolute mobility (the intercept), as the "same-sex attraction penalty/premium" at the lowest level of parental income. The difference in relative mobility (the slope) shows if and to what extent this premium/penalty depends on parental income.

²Mittleman (2022) questions whether same-sex attracted women maintain educational advantages in contemporary US samples.

³Note that the definition of "absolute mobility" varies across studies. In the terminology of Deutscher & Mazumder (2023), we refer to the conditional expected rank at the bottom of the parental income distribution (CER0) as absolute mobility.

Our first intergenerational analyses consider the rank-rank relationship between parental and adult children's labour market income. We find substantial differences in absolute mobility, with same-sex attracted men having lower income ranks compared to different-sex attracted men across the entire parental income distribution. Not even the same-sex attracted men from the most financially resourceful backgrounds overcome the "gay penalty". The premium for same-sex attracted women, on the other hand, decrease across the parental income distribution, with the largest premium for those growing up with the parents at the bottom of the income distribution. We also consider educational attainment and find no differences in relative mobility between different-sex attracted and samesex attracted individuals, rather, same-sex attracted individuals have higher educational attainment across the parental income distribution compared to different-sex attracted individuals of the same sex. As such, this does not offer an explanation for different-sex attracted men outperforming same-sex attracted men in intergenerational mobility in terms of earnings. Our income residual analyses reveal that same-sex attracted individuals experience not only different mean income levels, but their income levels also vary to a larger extent.

When considering household income for same-sex attracted women, we see that a combination of fewer years in relationships and the overall lower earnings of women result in a striking gap in absolute mobility equivalent to more than -18 rank points at the intercept and widening across the parental income distribution compared to different-sex attracted women. As such, what is gained individually is lost manifold at the couple-level. For same-sex attracted men, household income at the intercept is roughly equal to that of different-sex attracted men but falling increasingly behind as parental income rank increases. We show that the reason for this is a combination of lower earnings (relative to different-sex attracted men), longer time spent out of relationship, and less assortative matching.

Next, we consider fertility through an intergenerational lens. In recent years, there has been a rise in the number of families headed by two parents of the same sex in countries where the legal environment permits this (Evertsson et al., 2023). This has made quantitative research on same-sex attracted individuals' fertility behaviours possible (Andresen & Nix, 2022; van der Vleuten et al., 2024), as well as studies of the outcomes of the children growing up in these families (Mazrekaj et al., 2020; Manning et al., 2014). These studies show that same-sex attracted men are particularly unlikely to become parents (Badgett et al., 2021). As same-sex couples endure legal and practical barriers to parenthood that are likely easier to overcome by those with more financial means, fertility rates may be

higher among those whose parents are most financially resourceful. Indeed, we find this pattern for same-sex attracted women, although, even at the high end of the parental income distribution, they are still far less likely to have children compared to different-sex attracted women. The absence of children, and thus, absence of child penalties in earnings (see e.g. Kleven et al., 2019; Adams et al., 2024), may contribute to their higher individual income. Like with income, fertility differences between same-sex attracted and different-sex attracted women are particularly pronounced at the low end of the parental income distribution. Less than 5% of all same-sex attracted men have children by their 35th year of life, and we see a marginal but significant decrease across the parental income distribution. This highlights that barriers to parenthood for same-sex attracted men are not easily mitigated by financial resources.

We progress to consider health outcomes, focusing on medical prescriptions and health visits to private practitioners and hospitals. For decades, mental health has been identified as a particular area of concern for sexual minorities. A recent meta-analysis of populationbased studies found that the risk of depression and anxiety in same-sex attracted individuals is more than double that of different-sex attracted individuals (Wittgens et al., 2022). Many studies have ascribed this increased risk of mental health issues to "minority stressors" in the environment, such as discrimination or prejudice events (Meyer, 1995). We find that both same-sex attracted men and women are more likely to have been prescribed mental health medications and visit psychiatric hospitals compared to different-sex individuals of the same sex – this is true across the entire parental income distribution. When considering psychiatric hospital visits, reflecting more serious cases of mental health conditions, we find that the gap widens between same-sex attracted and different-sex attracted individuals at the bottom of the parental income distribution. In other words, same sex-attracted individuals of the lowest earning parents are not simply facing a fixed same-sex penalty together with an increased risk associated with low parental income - here, the intersection of being same-sex attracted and having low parental income yields an additionally increased risk of serious mental health conditions. We find few differences in terms of physical health, and most of these are likely to be explained by the different fertility-related behaviours of different-sex attracted and same-sex attracted individuals.

In our last set of outcomes, we consider the parent-child relationship and examine moving-out age and geographical proximity. Same-sex individuals are less likely to live near parents across all parental income levels, especially same-sex attracted men from lowest-income families. This may reflect a potential mechanism, as less time spent in near

proximity to parents could limit available parental support (Hünteler & Mulder, 2020).

We use a simplified Oaxaca-Blinder decomposition to show that differences in absolute (rather than relative) mobility generally explain more of the intergenerational gaps between same-sex and different-sex attracted individuals. This informs our heterogeneity analyses, in which we explore differences in absolute mobility across cohorts and regions. These analyses show that the income premium of same-sex attracted women disappear in younger cohorts together with their relatively higher educational attainment, and as they become more likely to have children. In contrast, we see that disparities in mental health (which are generally smaller for same-sex attracted men growing up in the capital) increase in younger cohorts, further widening the mental health gap between same-sex and different sex attracted individuals.

Finally, we exploit sibling links in the Danish data and extend our analyses of absolute mobility by controlling for sibling fixed effects (FEs). This exercise is possible because sexuality tends to vary between siblings, unlike previous stratifiers in intergenerational mobility research, such as race and immigration status. The inclusion of sibling FEs controls non-parametrically for family characteristics beyond parental income, such as variation in genetics and family environment. Thus, our sibling FEs strategy yields estimates of differences by sexuality that approach the causal effect of sexuality on outcomes in early adulthood. All estimates of absolute mobility gaps between same-sex attracted and different-sex attracted individuals are similar to the effects we find by including sibling FEs, suggesting that the causal effects of the difference in sexuality on various outcomes are close to the effect of the difference in absolute mobility. The fact that our results are robust across specifications with and without sibling FEs also offers support to previous and future findings on the outcomes of sexual minorities, including those that are based on less comprehensive data sources that do not allow for fixed-effects approaches.

Beyond gender, the existing literature on intergenerational mobility tends to highlight the mobility-altering role of factors shared by siblings, e.g. neighbourhoods and regions (Chetty & Hendren, 2018; Eriksen & Munk, 2020), race (Chetty et al., 2020), and parental migrant status (Abramitzky et al., 2021; Boustan et al., 2025; Jensen & Manning, 2025). By identifying sexuality as a key dimension of absolute intergenerational mobility, our results show that intergenerational mobility depends not only on factors shared by siblings but also on innate individual characteristics, such as sexuality, in addition to child gender. As such, our results carry significant implications for policy by highlighting that interventions aimed at improving the outcomes of future generations must also address sexuality-specific

barriers to intergenerational mobility. If not, we are likely to see a further widening of the mobility gap between same-sex attracted and different-sex attracted individuals, e.g., in the labour market and in mental health.

The rest of this paper is organised as follows. Section 2 describes the institutional setting and data, including how we observe same-sex and different-sex couples. Section 3 provides descriptive statistics. Section 4 includes estimates of differences in intergenerational mobility between same-sex attracted vs. different-sex attracted individuals and explores potential underlying dynamics. Section 5 decomposes the gaps in outcomes, formally showing to what extent the gaps are due to differences in absolute or relative mobility. Section 6 further explores selection by parental background by controlling for sibling FEs. Section 7 explores heterogeneity across regions and cohorts, and extends our rank-rank analyses by also considering variation income outcomes along the parental income distribution. Finally, Section 8 concludes.

2 Institutional setting and data

For all our analyses, we rely on administrative data from Denmark which cover the entire Danish population. Before describing these data in detail, we first summarise the institutional context in Denmark, considering both the legal rights and recognition of same-sex couples as well as more general policies like access to health care. Many of the relevant administrative datasets start in 1980 and are available until 2022. To observe cohabitation of same-sex and different-sex couples, we rely on data on financial commitments, which are available from 2003 onward. Importantly, individuals and their parents can be linked and tracked over time, so when we observe a 34-year-old in a cohabiting relationship in 2015, we can link them with their parental income in the 1980s.

In our data description, we start by outlining our data on child outcomes and how we construct our population-wide measure of cohabiting couples. We continue by validating our couples measure and relate it to alternative measures of couples and sexuality. Finally, we describe our data on parental characteristics.

2.1 Institutional setting

Throughout the paper, we consider fertility and health outcomes. Therefore, it is important to understand that Denmark is generally a country with a high level of government support for families with children, and that health care is almost exclusively provided at no or low cost at the point of use (see e.g. Danish Ministry of Health, 2017; Olejaz et al., 2012, for details on the health care system).

In Denmark, consultations with GPs and specialist practitioners as well as hospital care involve no costs for patients. Specialist practitioners care for patients in need of specialist care that cannot be handled by a GP, but not with symptoms sufficiently acute or severe to require hospital treatment. There are two main exceptions to the free health care provision as patients pay co-payments on: 1) prescriptions for medicine up to a certain threshold (DKK 4,110 \approx USD 590 in 2019) and 2) treatment by psychologists, physiotherapists, and similar care not provided by medical doctors. However, if people are sufficiently incomeconstrained, municipalities tend to cover these costs.

Fertility is financially incentivised through multiple government policies in Denmark, including: 1) extensive parental leave with high salary replacement rates (see e.g. Jørgensen & Søgaard, 2024), 2) a high level of child benefits independent on income (see e.g. Jensen & Blundell, 2024), and 3) heavily subsidised childcare with local municipalities typically covering 75% or more of the cost of childcare until school age (see e.g. European Commission, 2022; Naumann et al., 2013). Schooling at all levels, including high school and university, is provided at no cost. As such, the direct costs of having children are relatively low in Denmark.

Today, subsidised fertility treatment is available for different-sex couples, single women, and women in same-sex relationships, but this has not always been the case. Like it is the case in other Western European countries, same-sex couples in Denmark only recently gained basic legal rights. Denmark was the first country in the world to legalise same-sex registered partnerships in 1989 (Søland, 1998). In 2012, same-sex couples obtained equal rights to civil marriage, as well as marriage within the Danish state church. Since 1999, it has been possible, under certain circumstances, for a same-sex partner to adopt the (potentially adopted) child of their partner, but not until 2010 could same-sex couples adopt jointly (Kjær, 2017). Although the right to adoption has technically been the same for same-sex couples (and single individuals) as for different-sex couples since 2010, a number of practical barriers significantly limit access to adoption for same-sex couples. Hence, between 2011-2020, only 175 native children were put up for adoption in Denmark, and only one other country (South Africa) has ever allowed same-sex couples from Denmark to adopt (Adoptionsnævnt, 2024; Danish International Adoption, 2021). Surrogacy was technically unregulated in Denmark until 1997, but evidence suggests that only very few same-sex couples (of which only one person could be registered as a parent of the child at the time) have ever made use of this (Nordisk Ministerråd, 2006). Since 1997, surrogacy has effectively been prohibited in Denmark. Although individuals are legally allowed to act as surrogates, they

are not allowed to undergo fertility treatment, neither within the public healthcare system nor at a private clinic (thus requiring the surrogate to be the biological parent of the child as well as insemination to happen without any assistance). Additionally, surrogates are not allowed to receive financial compensation (Indenrigs- og Sundhedsministeriet, 2019), and it is a criminal offence to advertise for a surrogate, whether this is done directly by the intended parents or through third parties (Social- og Boligministeriet, 2019). As such, a number of legal and practical barriers still limit access to parenthood for (especially male) same-sex couples in Denmark.

2.2 The children

For all the analyses that follow, we consider all children born in Denmark from 1974 to 1988.⁴ Our latest data are from 2022 allowing us to observe our latest cohort in their 35th calendar year of life (i.e. the calendar year in which they turn 34). When considering labour market outcomes, such as income and unemployment, we need to observe children when they are sufficiently old to have finished education. We therefore observe labour income and public transfers/benefits from the children's 30th to 35th year of life, i.e. over six years (in the IND-register, we adjust all measures of income for inflation). Child income ranks are subsequently determined within each child cohort of the population, following Chetty et al. (2020). For each adult child, we also calculate an average unemployment rate from their 30th to 35th year of life (employment status is from the AKM-register).

We also consider several demographic outcomes for the adult children: marriage, parental status, home region, and education level (in the BEF- and UDDA-registers). We observe all of these outcomes in the children's 35th year of life. When comparing the years spent in cohabiting relationships, we once more examine the six years from the children's 30th to 35th year of life.

Next, we consider a variety of health outcomes. Measures of all health outcomes are available from 1995 onwards. To consistently measure health outcomes over the same age range for each child cohort, we consider health outcomes from 22nd to 35th year of life (those born in 1974 are observed in their 22nd year of life in 1995). We observe all medical prescriptions for contraceptives, opioid painkillers, non-opioid painkillers, and prescriptions related mental health conditions and substance abuse (in the LMDB-register). We also observe visits to hospitals, and whether each visit takes place at a hospital ward specialised in the treatment of psychiatric or somatic conditions (LPR_ADM, PSYK_ADM and LPR_F_FORLOEB). For each hospital visit, we use precise diagnostic codes to determine if

⁴We exclude children born abroad, as we need to be able to observe parental income in childhood.

the visit is related to substance abuse (LPR_DIAG, PSYK_DIAG, and LPR_F_DIAGNOSER). Finally, we observe patient visits to non-hospital practitioners, including GPs, psychologists, and psychiatrists (SYSI/SSSY). Non-hospital practising psychiatrists tend to care for patients with less acute and less complex conditions that do not require in-patient care.

2.2.1 Observing couples and sexuality

To obtain a population-wide indicator of sexuality, we want to identify cohabiting couples, and importantly, distinguish these couples from housemates. Based on the sex composition of an observed couple, we can infer an individual-level measure of sexuality. However, statistical agencies typically classify two cohabiting people of different sexes as a couple and same-sex cohabitants as housemates (Statistics Denmark, 2024; Statistics Finland, 2024). This induces misclassification because same-sex couples make up a non-negligible share of the population, and because housemates can be of different sexes. In the following, we describe how we overcome this limitation and observe couples (different-sex *and same-sex*) at the population-level.

To identify couples, we first need to identify two-adult households. To do so, we use the Danish population register (BEF) from 2003 to 2022 in which we observe the full Danish population and the address at which they reside. We concentrate on individuals residing at the same address (house/apartment) and exclude very large households.⁵ Next, we remove children (retaining only the parent generation in multi-generational households) and exclude sibling pairs. We focus on all remaining two-adult households, which can either be cohabiting couples or housemates.⁶

To overcome misclassification and to identify same-sex cohabiting couples, we use recently released population-level data covering 2003-2022 on individuals' financial commitments. We use data on shared bank accounts (IRTEPERS/URTEPERS), joint bank loans and mortgages (PANTPERS), and jointly owned properties (EJER) from Statistics Denmark. We identify all financial commitments with two registered owners.

We can now separate our two-person households into cohabiting couples and housemates by exploiting that almost all cohabiting couples in Denmark have at least one shared financial commitment (data validation follows in Section 2.2.2). As such, we classify a twoadult household as a couple only if they share at least one financial commitment. We sup-

⁵With more than 10 people living at the same address; these are typically institutionally provided housing. ⁶To avoid households made up by an individual and, e.g., a step-parent who would not be legally registered as the individual's parent but with whom they share financial responsibilities, we do not consider a two-person household a couple if the age-difference is greater than 12 years (corresponding to the 95th percentile). In addition, we focus on people in cohabiting couples when they are older than 25 to exclude other cohabitation with potential caregivers.

plement the data on financial commitments by also classifying two-adult households as couples if they are married to each other or if they are legal parents of the same child.

We use the legal sex (which in Denmark is strictly binary, i.e., male or female) of each individual in a couple to derive a measure of sexuality at the individual level. Men who are observed in couples with women and, similarly, women observed in couples with men, we refer to as *different-sex attracted*. Men observed in couples with men, and women observed in relationships with women, we refer to as *same-sex attracted*. We also observe a small number of individuals who have lived in cohabiting couples with people of different sexes across two or more relationships. In our main analyses, we exclude this group as the small sample size rules out reliable statistical inference on intergenerational relationships in outcomes. We do, however, report various descriptive statistics for this group in Appendix B. We discuss the exclusion of this group in further detail in Section 2.2.3.

In our intergenerational analyses, we consider all children born in Denmark from 1974 to 1988. Our final sample of children includes those we observe in at least one cohabiting relationship at some point from 2003 to 2022. We identify a total of 823,219 adult children born in Denmark from 1974 to 1988, and we observe 83% of those in at least one cohabiting relationship with a financial or legal commitment. Of these, 1%, or 6,922 individuals, are observed exclusively in same-sex relationships, and 99%, or 671,412 individuals, exclusively in different-sex relationships. This distribution largely mirrors estimates from a significant cohort study focused on sexuality and sexual health in Denmark, in which 1.1% of respondents identified as gay or lesbian (Frisch et al., 2019). We outline the characteristics of our sample in detail in Section 3.

2.2.2 Measurement validation

We undertake a number of validation exercises to test the validity of our new population-wide measure of sexuality. The details of these are available in Section A.1 in the Appendix. Here we provide a brief overview.

First, we show that shared financial commitments are highly prevalent among cohabiting couples who are married or parents of the same child, regardless of the sex composition of the couple. This shows that same-sex and different-sex couples observed through more conservative methods, i.e., marriage and co-parenthood, are equally likely to share financial responsibilities.

Second, we compare the number and age distribution of observed cohabiting individuals with and without conditioning on shared financial commitments. This indicates that conditioning on financial commitment is instrumental in distinguishing between housemates

and cohabiting partners.

Third, we consider relationship trajectories and show that the majority continues to partner with individuals of the same sex as their first observed partner, with many transitioning to marriage and co-parenting. This further supports the correct identification of cohabiting couples.

Fourth, we consider prescription contraceptive use among women in different types of cohabiting households and find further evidence that we correctly identify couples.⁷ As expected, we find that women in same-sex relationships are generally less likely to use contraceptives, and we find no differences in contraceptive use between women in same-sex relationships based on the route of identification (marriage vs. joint child vs. cohabitation with joint financial commitment). For women with different-sex partners, contraceptive use varies substantially between various types of different-sex relationships, reflecting a decrease in contraceptive use when couples plan pregnancies.

Finally, in Section 3, we describe how the differences in mean outcomes between our samples of same-sex and different-sex attracted individuals align with those of previous studies from diverse contexts (including the paradoxical finding of higher education, but lower earnings for same-sex-attracted men). These descriptives lend further creditability to our new measure of sexuality.

2.2.3 Measurement discussion

By observing joint financial responsibilities, we overcome some of the key data limitations to identify (especially same-sex) couples in population data appropriate for intergenerational analyses. As such, our measure of sexuality is not sensitive to the inconsistent terminology that may arise when using self-identification measures of sexual identity (Julian et al., 2024b), nor to differential sorting into marriage for people of different sexualities (Manning et al., 2022; Compton & Kaufman, 2024). We address potential concerns regarding selection into cohabitation and the uptake of financial commitments in Section 6.

Generally, sexuality tends to be observed in quantitative data in two ways: self-identification measures and behavioural measures. Behavioural measures can be based on sexual history or the sex of one's spouse; the latter has the advantage of being available through marriage registers in administrative datasets. Regardless of the choice of strategy, behavioural measures do not provide accurate measures of sexual *identity*. Firstly, because sexual and romantic behaviour does not necessarily correspond to a person's desires, as

⁷We only use women's contraceptives as these are recorded in population-wide data on medical prescriptions. Female contraceptions typically require prescriptions (e.g. pills and IUD's).

they may decide not to, or fail to, live these out. Second, and even more importantly, terms used for self-identification of sexuality mean different things to different people. As such, the same term may refer to a range of experiences. Examples of this include straight men who regularly have sex with other men (Silva, 2017). Therefore, behavioural measures and self-identifying measures of sexuality do not identify the same individuals as same-sex attracted and, as a consequence, nor the same sample characteristics within the same data set (Martell & Eschelbach Hansen, 2017; Mishel, 2019; Curley, 2018). The increasing diversity in gender and sexual identities, especially in younger cohorts, has led researchers specialising in the measurement of sexuality and gender to suggest the inclusion of questions related to couples' gender composition and cohabitation to construct behavioural measures of sexuality within surveys, even when self-identification questions are available (Julian et al., 2024a,b). Although cohabiting couples may be identified in survey data, identification remains difficult in datasets that cover an entire population. Census data may include information on both sexual identity and the gender of cohabiting partners, but in a census, cohabitation is only observed once. As same-sex relationships may be shorter (Lau, 2012), and there are breaks between relationships, same-sex couples will be observed less frequently in the cross-section. Therefore, repeated observations of couples allow for a more accurate identification of same-sex attracted individuals. We explore such household dynamics directly in our data in Section 4.3.

The same-sex attracted individuals we observe in our data all have a history of cohabiting relationships or marriage with someone of the same sex. This has the same advantages as previous behavioural strategies without suffering from the unequal access or differential sorting into marriage of same-sex attracted and different-sex attracted individuals. We believe this is an advancement from previous behavioural measures of same-sex attraction because it effectively identifies cohabiting same-sex couples. However, as all measures of sexuality, our measure has limitations.

Firstly, our measure does not capture the multitude of ways in which individuals may organise relationships (Compton & Kaufman, 2024). For example, we cannot observe the sexuality of individuals who never form romantic relationships that lead to cohabitation (we provide descriptive information on this group in Table B.4).

Second, we do not assess sexual identity, so we cannot distinguish between identity categories such as gay/lesbian, bisexual/pansexual, and heterosexual. For the same reason, we adopt the terminology "same-sex attracted" and "different-sex attracted". We focus our analyses on individuals who have only been in either same-sex or different-sex relation-

ships, thus excluding individuals observed with both female and male partners across different relationships. This is primarily because of the limited sample size of the bi-attracted group, but also because the observation of this group relies on the observation of more than one cohabiting relationship, whereas we can observe same-sex and different-sex attraction as soon as an individual has entered *one* cohabiting relationship. Thus, some of the individuals we observe as different-sex attracted or same-sex attracted will experience attraction towards people of various sexes, just as a minority of those who identify as gay or lesbian may enter different-sex relationships later in life (Mernitz et al., 2024).

Finally, as we observe sex based exclusively on legal sex (which is strictly binary in Denmark), our analyses cannot capture gender identity. This limitation means that the sexuality of individuals who do not identify within the gender binary, as well as of the non-negligible share of trans individuals who have not changed their legal sex (Thomsen et al., 2024), will also be inferred based on their and their partner's legal sex.

2.3 The parents

Our primary parental characteristic is labour market income in the first 21 years of children's lives (from the IND-register).⁸ For all analyses, we consider the sum of parental labour income of both parents. After adjusting parental income for inflation and taking the sum over the relevant 21 years, we rank parental income from 0 to 100 within child cohorts. This approach follows that of Chetty et al. (2014), but we take advantage of the fact that the Danish data on parental income are available further back in time, allowing us to consider parental income throughout children's upbringing.

In addition, we consider the age at which children cease to live at the same address as their parents, and whether children reside in the same region as at least one parent by their 35th year of life. We observe potential cohabitation with parents and parental home region in the BEF-register, spanning 1985 to 2022.⁹

3 Descriptive analyses

In Table 1, we present all outcomes included in the intergenerational analyses, alongside relevant parental characteristics by sex and sexuality. This provides an overview before we

⁸Danish income registers only start in 1980. For our earliest cohorts, born in 1974 to 1979, we therefore do not observe parental income in the very first years of life. For example, for those born in 1974, we observe parental income from 1980 to 1994, year 7 to year 21. Parental income ranks are determined within child cohorts to reflect this.

⁹As BEF is only available from 1985, information on children's cohabitation with their parents is not observable prior to age 11 for our first child cohort, born in 1974. As such, when considering the age of the child when ending cohabitation with parents, we truncate the values below 11 and set them equal to 10 for all cohorts for consistency.

advance to the intergenerational analyses. Given our new strategy for identifying samesex attracted individuals, these descriptives also offer new evidence on the characteristics of same-sex attracted individuals at the population level.

We generally divide child outcomes and parental characteristics into five broad categories: 1) labour market outcomes and education, 2) health outcomes, 3) family and household characteristics of the adult children, 4) parental characteristics, and 5) parent-child relationship dynamics. We consider differences in means across the five categories below.

Labour market and education: Table 1 reveals contrasting labour market outcomes by sex and sexuality. Same-sex attracted women earn more than different-sex attracted women (+3.11 percentile points, or 11,820 DKK annually) and achieve higher educational attainment, despite similar unemployment rates. Different-sex attracted women receive more public benefits, likely reflecting higher fertility rates and associated maternity leave and child benefits.

In contrast, same-sex attracted men earn substantially less than different-sex attracted men (-4.51 percentile points, or -22,735 DKK annually), despite higher educational attainment and lower fertility rates. They experience slightly higher unemployment rates, receive fewer unemployment benefits, but more public benefits overall – a pattern consistent with lower fertility (fewer parental leave benefits) and more years of education (more educational benefits).

These findings mirror previous research identifying a "lesbian pay premium" and "gay pay penalty" alongside higher educational attainment for both same-sex attracted groups (see Badgett et al., 2024, for review). We believe this provides further evidence of the validity of our method for identifying couples, based on the observation of shared financial commitments.

Health: General health visit patterns largely reflect fertility differences. Different-sex attracted women have more GP visits and non-psychiatric hospital admissions than same-sex attracted women, but these differences disappear when excluding fertility-related visits, indicating that fertility drives the differences. Conversely, same-sex attracted men visit GPs more frequently but have fewer non-psychiatric hospital admissions than different-sex attracted men.

Mental health outcomes reveal consistent disparities. Same-sex attracted individuals of both sexes show substantially higher rates of mental health service use and prescriptions, aligning with established evidence of elevated mental health risks among sexual minorities (see Wittgens et al., 2022, for meta-analysis). Same-sex attracted women are more

Notes: This table reports means of outcomes by sex and sexuality. Numbers in parentheses state the years in which an outcome is observed, i.e., 30-35 refers to the 30th-35th years of life. For parental outcomes, numbers in parentheses refer to child years of life. Income measures are inflation-adjusted to 2015-levels. Max years living with parents refers to the year last observed living in a household with parents until year 35. See Section 2 for further details on variables and data construction. * p < 0.1, ** p < 0.05, *** p < 0.01

likely to receive treatment from psychologists and psychiatrists, to have psychiatric hospitalisations, and to receive mental health prescriptions compared to different-sex attracted women. They also show higher rates of substance abuse, alcohol abuse, and opioid-related treatments, and receive more opioid and non-opioid analgesics. Similar trends are observed at the intensive margin across all mental health outcomes, although these are not statistically significant for counts of opioid abuse and substance abuse prescriptions.

Same-sex attracted men exhibit similar patterns of elevated mental health service use, with one notable exception: they are less likely than different-sex attracted men to receive substance and alcohol abuse treatments.

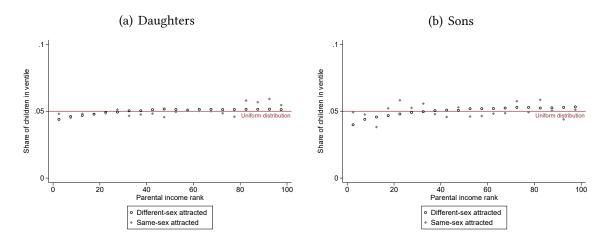

Family and household: Table 1 shows that same-sex attracted individuals are less likely to marry or have children, and more likely to live in the capital than their different-sex attracted counterparts. These differences are particularly stark for men: same-sex attracted men are nearly twice as likely to live in the capital region, whilst different-sex attracted men are over 16 times more likely to have children. Women show smaller but still substantial and significant differences. Beyond their demographic interest, these patterns highlight the advantages of identifying same-sex attracted individuals through cohabitation and joint financial commitments rather than marriage and parenthood alone.

Same-sex attracted individuals spend less time in cohabiting relationships – particularly men – compared to different-sex attracted individuals. This contributes to lower household incomes for same-sex attracted individuals, alongside substantially lower mean partner incomes. However, the mechanisms differ by sex. For same-sex attracted men, lower unconditional partner income stems primarily from longer periods outside relationships: when restricting to years in relationships, same-sex attracted men's partners earn significantly more than different-sex attracted men's partners (i.e., women). Conversely, same-sex attracted women's partners earn less than different-sex attracted women's partners (i.e., men) even when considering only relationship years. These patterns reflect broader sex income differences, where female partners typically earn less than male partners regardless of relationship type.

Parental characteristics: Table 1 reports very similar parental income ranks for same-sex and different-sex attracted children (albeit slightly lower for same-sex attracted men). In Figure 1, we further explore potential differences in selection by parental income by plotting the distribution of same-sex attracted and different-sex attracted individuals across the parental income distribution. Parental income distributions are based on parental earnings from the child's 1-21 years of life and are ranked within child cohorts. Figure 1 shows a near

identical distribution of children by sexuality (same-sex vs. different-sex). However, Table 1 indicates that, on average, mothers of same-sex attracted women have slightly higher labour market income compared to mothers of different-sex attracted women. For men, we find the reverse, with Table 1 showing a higher average maternal income rank among different-sex attracted men compared to same-sex attracted men; however, the differences are small.

Figure 1: Distribution of same-sex and different-sex attracted individuals across parental income ventiles

Notes: This figure plots the share of different-sex and same-sex attracted children in each the parental income ventile. We consider children born from 1974 to 1988. Same-sex/different-sex attraction is determined by observing cohabiting relationships with at least one financial commitment; see Section 2.2.1 for details. Parental income is measured over 21 years (1st-21st year of each child's life). All income measures are inflationadjusted, and income ranks, 0-100, are determined within child cohorts. See Section 2 for details on data construction and variables.

Parent-child dynamics: We examine parent-child relationship dynamics through two measures: age at leaving the parental home and geographical proximity to parents in adult-hood. Regarding age at leaving the parental home, we find contrasting patterns by sex. Same-sex attracted women leave home later than different-sex attracted women (by 0.76 years), whilst same-sex attracted men leave earlier than different-sex attracted men (by 0.71 years). For geographical proximity in the 35th year of life, same-sex attracted individuals – particularly men – are consistently less likely to live near their parents than different-sex attracted individuals across all three geographical levels examined.

4 Estimates of intergenerational mobility by sexuality

After documenting substantial differences in mean outcomes between same-sex and different-sex attracted individuals, we want to explore to what extent these differences de-

pend on parental background, and particularly, on parental income. As such, we want to assess whether intergenerational mobility in terms of earnings, demographic outcomes, health, and parent-child dynamics differ between adults depending on their sexuality. When estimating differences in intergenerational mobility by sexuality, we generally follow the strategy of Chetty et al. (2020) and Boustan et al. (2025) who compare intergenerational mobility across race and parental immigration status. Their strategy enables us to consider separately the differences in both absolute and relative mobility as we estimate the following specification for daughters and sons, respectively:

$$y_{i,c} = \alpha + \beta_p y_{i,p} + \beta_s \operatorname{same_sex}_i + \beta_{sp} y_{i,p} \cdot \operatorname{same_sex}_i + \varepsilon_i \tag{1}$$

where $y_{i,c}$ is the outcome of interest of the adult child, e.g. their income rank, parental income rank is denoted by $y_{i,p}$, and same_sex_i for same-sex attraction. α represents the level of absolute mobility and β_p relative mobility for different-sex attracted. In our comparison between different-sex and same-sex attracted individuals, lower/higher absolute mobility is given by the difference in the intercept, β_s . Differences in relative mobility (the slope of the rank-rank relationship) is given by β_{sp} . Generally, we can interpret differences in the intercept, β_s , as what is often referred to as the "gay/lesbian penalty/premium" at the lowest level of parental income. The difference in slopes, β_{sp} , shows if and to what extent this premium/penalty depends on parental income.

We consider a wide range of outcomes, $y_{i,c}$, ranging from income ranks to the use of mental health prescriptions. When considering income, we calculate income ranks for both children and parents within child cohorts, capturing any beyond-inflation trends in income across cohorts. However, other outcomes, such as the extensive margin use of mental health prescriptions, cannot be naturally ranked within cohorts, and results may be affected by trends across cohort. Thus, we report results including cohort FEs as controls throughout Appendices C to D. Furthermore, we consider an extension to the model when controlling for unobserved parental heterogeneity by including sibling FEs in Section 6.

4.1 Individual outcomes

4.1.1 Labour market outcomes and education

Figure 2 illustrates intergenerational mobility in terms of labour market outcomes and educational attainment for men and women based on their sexuality. Panel (a) shows the income rank of different-sex attracted and same-same attracted individuals across the parental income distribution. For women we see that those who are same-sex attracted show higher absolute mobility compared to different-sex attracted women, with a 4.70 higher rank at the intercept compared to different-sex attracted women. Same-sex attracted

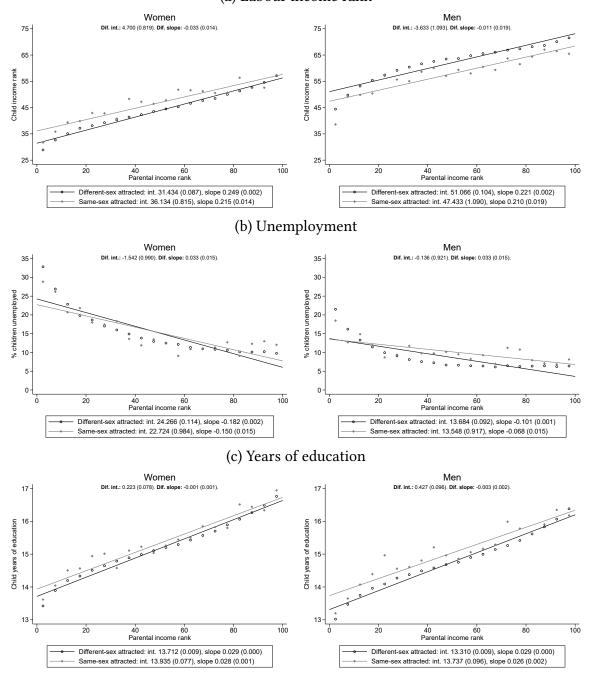

women also have slightly higher relative mobility (a flatter rank-rank slope) and therefore, the earnings gap narrows as parental income increases. Together, this shows that the "lesbian premium" found in previous studies of the labour market outcomes of sexual minorities exists across the entire parental income distribution but to a decreasing degree as parental income increases. Hence, the premium for same-sex attracted women is particularly pronounced for those with parents at the lowest end of the income distribution (see e.g. Klawitter, 2015, for an overview of estimates of earnings gaps by sexuality). We find no difference in relative mobility between same-sex attracted and different-sex attracted men, but we see a difference in absolute mobility, with a higher level for different-sex attracted men corresponding to a percentile rank difference of 3.56. Hence, we find lower earnings for same-sex attracted men across the entire parental income distribution, showing that even the same-sex attracted men who grow up with the most financially resourceful parents do not overcome the "gay penalty" in mean earnings (Klawitter, 2015). Despite the relatively lower earnings of same-sex attracted men and the relatively higher earnings of same-sex attracted women (compared to different-sex attracted individuals of the same sex and same parental income), the overall "gender pay gap" persists with men earning more than women across the entire parental income distribution regardless of their sexuality (see e.g. the review by Blau & Kahn, 2017). As such, different-sex attracted women represents the lower extreme and different-sex attracted men represents the higher extreme when considering the absolute mobility in terms of income.

Panel (b) considers unemployment as the differences in Panel (a) could be driven by the extensive margin. Panel (b) shows no differences between same-sex attracted individuals and different-sex attracted individuals in absolute mobility, offering no explaining for the differences in absolute mobility in terms of income. We find minimally higher relative mobility in terms of unemployment for same-sex attracted women compared to different-sex attracted men compared to different-sex attracted men.¹⁰

Another potential driver of the differences in absolute mobility in terms of earnings is educational attainment, given the positive financial returns to education (Blundell et al., 2005; Björklund & Salvanes, 2011). In Panel (c) we therefore consider child years of education across the parental income distribution. We observe that women generally have higher educational attainment than men, and that same-sex attracted women have higher educational attainment across the parental income distribution compared to different-sex

¹⁰Note from the plotted ventile means that the relationship between parental income and child unemployment is particularly non-linear for all groups. We reach similar conclusions when considering the non-linear relationships.

Figure 2: Intergenerational mobility, income and human capital (a) Labour income rank

Notes: In this figure, we plot estimates of Specification 1. We consider children born from 1974 to 1988. Same-sex/different-sex attraction is determined by observing cohabiting relationships with at least one financial commitment; see Section 2.2.1 for details. Child income is measured over 6 years (30th-35th year of life), child education level in the 35th year of life, and parental income over 21 years (1st-21st year of each child's life). All income measures are inflation-adjusted, and income ranks, 0-100, are determined within child cohorts. See Section 2 for details on data construction and variables. Standard errors in parentheses; see Tables C.6 to C.12 for point estimates from all specifications.

attracted women. Similarly, same-sex attracted men have higher educational attainment than different-sex attracted men across the parental income distribution. We find no significant differences in relative mobility when considering education. This confirms the finding from previous studies that same-sex attracted individuals have higher educational attainment (Badgett et al., 2024), but we add to this by demonstrating that the higher mean educational attainment of same-sex attracted individuals is not solely driven by those who grow up with the most financially resourceful parents; even same-sex attracted children from the bottom of the parental income distribution outperform their different-sex attracted peers with respect to education. The higher educational attainment among same-sex attracted women may contribute to their relatively higher earnings. However, as same-sex attracted men also outperform different-sex attracted men in terms of education across the parental income distribution while facing an equally consistent income penalty, differences in intergenerational mobility in terms of earnings do not merely reflect differences in education.

4.1.2 Health

Health has been identified as an area of particular concern for sexual minorities (Zeeman et al., 2019), but, as is the case for income and educational attainment, health disparities have been observed at the mean and have yet to be explored from an intergenerational perspective relative to parental income. At the same time, health and earnings are linked through a bidirectional relationship, as poor health may negatively affect labour market outcomes (Halla & Zweimüller, 2013) and vice versa (Thomson et al., 2022). Thus, examining the health of sexual minorities within an intergenerational framework may provide insights into both the mechanisms contributing to the increased risk of health conditions among sexual minorities and the differences in intergenerational mobility of earnings.

In Figure 3, Panel (a), we consider the total number of GP visits from the 22nd to 35th year of life, and we see a substantial difference in the absolute mobility of women, with different-sex attracted women having substantially more GP visits at the intercept (β_s = 29.49) across the entire parental income distribution. This should be viewed in light of the significantly higher fertility rates among different-sex attracted women, as pregnancy increases the demand for GP visits. Furthermore, as shown in Section 2.2.2, different-sex attracted women demonstrate a notably higher demand for prescription contraceptives, necessitating monitoring GP visits. For men, we find the reverse, with equal levels of relative mobility, but with lower absolute mobility of same-sex attracted men (β_s = 10.48) resulting in a consistently higher number of GP visits across the entire parental income distribution for same-sex attracted men. We do not observe diagnoses for GP visits, and as such, we

consider other health outcomes to further understand these dynamics.

Figure 3, Panel (b), shows the number of somatic hospital visits, excluding fertility-related visits. For women, we see no differences between same-sex and different-sex attracted individuals, indicating that the higher number of GP visits among different-sex attracted women (for which we do not know the cause) is likely explained by differential fertility behaviours. We see that same-sex attracted men have fewer somatic hospital visits, again, across the entire parental income distribution compared to different-sex attracted men (β_s = 0.98), and also that they do not receive more prescription painkillers. As such, their higher number of GP visits across the parental income distribution is not likely to be related to an increased risk of somatic symptoms. In contrast, same-sex attracted women receive more painkiller prescriptions across the full parental income distribution despite their lower fertility rates (β_s = 1.10).

After considering the treatment of somatic health conditions, we turn to mental health. In Figure 4, Panel (a), we first show intergenerational mobility in terms of the uptake of mental health prescriptions. Prescriptions may be issued by an individual's GP (e.g., in cases of depression and anxiety) or a specialised medical doctor at a hospital or in private practice. We see substantially higher levels of mental health treatment among same-sex attracted individuals across the entire parental income distribution, but no differences in relative mobility. These results indicate a same-sex attraction mental health penalty that is not overcome irrespective of parental financial resources.

In Figure 4, Panel (b), we consider psychiatric hospital treatments which, compared to mental health prescriptions, indicate more serious or persistent cases of mental health conditions. For same-sex attracted individuals we again find substantially lower levels of absolute mobility (i.e., higher uptake of psychiatric hospital treatment) compared to different-sex individuals of the same sex, but now we also see a small but significant difference in relative mobility. This shows that the relatively higher demand for psychiatric treatment among same-sex attracted individuals increases as parental income decreases. For women, we see a similar pattern when considering hospital treatment related to substance abuse in Panel (c), with higher uptake of treatment among same-sex attracted women across the entire parental income distribution, but with the relatively higher risk further amplifying at the lower end of the income distribution. Thus, we find a persistent "mental health penalty" among same-sex attracted individuals regardless of parental income levels. However, the higher risk of *severe* mental health conditions at the lower end of the parental income distribution intersect with sexuality, resulting in same-sex attracted children from low-income

families being particularly likely to experience severe mental health conditions.

We present intergenerational analyses of other health-related outcomes in Tables C.7, C.8, and C.9 in Appendix C. We see similar trends in most outcomes, i.e., higher numbers of visits and prescriptions related to mental health across the entire parental income distribution when comparing same-sex attracted individuals to different-sex attracted individuals.

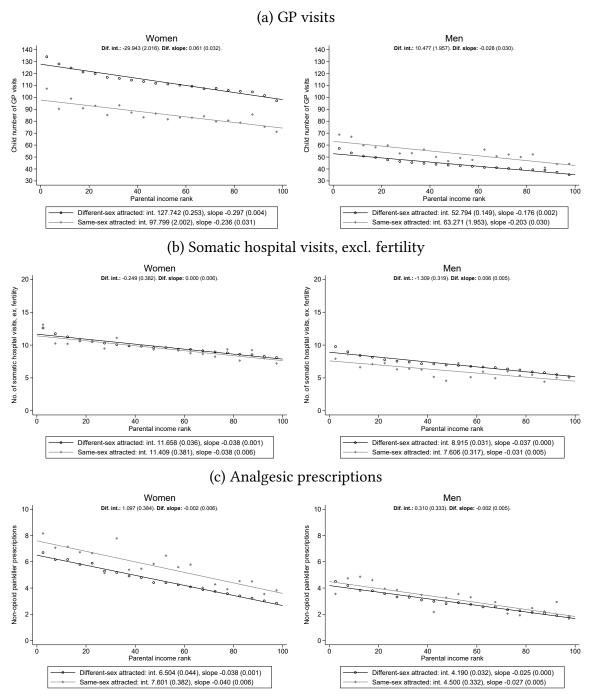

4.2 Household outcomes

4.2.1 Fertility

Having a child is a life-changing event with immediate and long-lasting effects on a person's daily life and on, especially mothers', earnings; this effect is often referred to as the "child penalty" (Adams et al., 2024; Kleven et al., 2019; Lalive & Zweimüller, 2009). The fertility outcomes of same-sex couples have captured the interest of researchers across disciplines, but this is yet to be studied through an intergenerational lens. Considering the fertility outcomes of same-sex and different-sex attracted individuals in relation to their parents' financial resources may not only help us understand the drivers behind the fertility behaviours of both groups (i.e., who becomes a parent and when?), but may also uncover mechanisms contributing to the intergenerational mobility gaps in income observed between these groups. In Figure 5, Panel (a), we consider the share of parents (i.e., among those we refer to as children in our intergenerational analyses). For different-sex attracted men and women, parental rates are consistently high, although slightly decreasing across the parental income distribution. The share of same-sex attracted women who are parents is substantially lower than that of different-sex attracted women; however, contrary to the latter, we observe an increasing probability of having a child across the parental income rank for same-sex attracted women, which may be partially explained by costly infertility treatments (see Groes et al., 2024). In Panel (b), we consider the number of children an individual has, conditional on being a parent. For women, we observe a pronounced absolute mobility gap at the intensive fertility margin, and the gap persists across the parental income distribution. Finally, in Panel (c), we see that across the entire parental income distribution, same-sex attracted women are more than two years older than different-sex attracted women when having their first child. Again, the difference is slightly larger at the lower end of the income distribution. As child penalties on women's lifetime earnings are particularly high for those who have their first child at a young age (Leung et al., 2016), the relatively older age of same-sex attracted women at first childbirth is likely to contribute to their comparatively higher earnings.

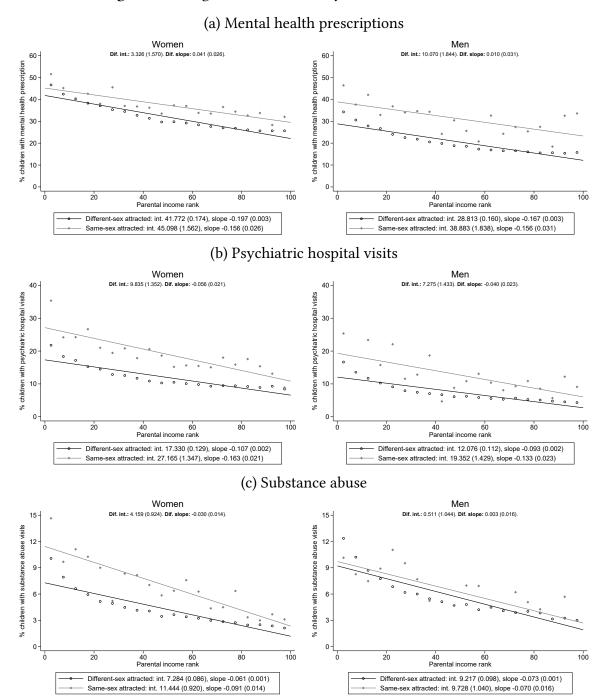

The higher age at first child, along with lower fertility at both the extensive and inten-

Figure 3: Intergenerational mobility, general health outcomes

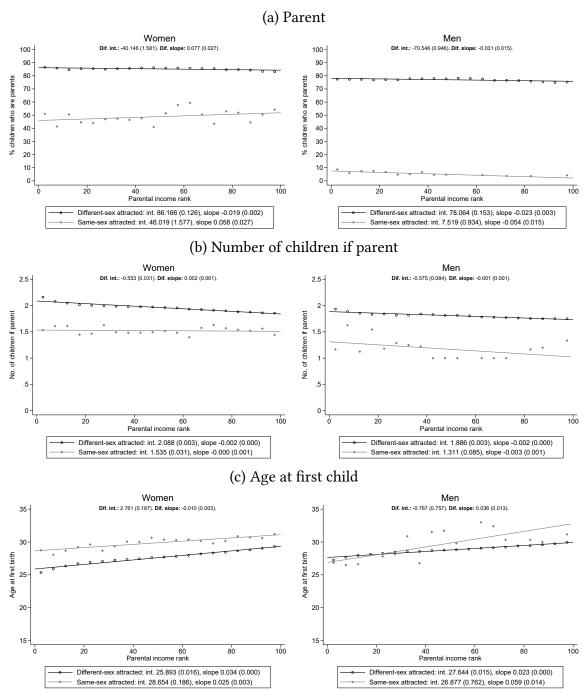

Notes: In this figure, we plot estimates of Specification 1. We consider children born from 1974 to 1988. Same-sex/different-sex attraction is determined by observing cohabiting relationships with at least one financial commitment; see Section 2.2.1 for details. Child health outcomes are measured from the 22nd to 35th year of life, and parental income over 21 years (1st-21st year of each child's life). All income measures are inflation-adjusted, and income ranks, 0-100, are determined within child cohorts. See Section 2 for details on data construction and variables. Standard errors in parentheses; see Tables C.6 to C.12 for point estimates from all specifications.

Figure 4: Intergenerational mobility, mental health outcomes

Notes: In this figure, we plot estimates of Specification 1. We consider children born from 1974 to 1988. Same-sex/different-sex attraction is determined by observing cohabiting relationships with at least one financial commitment; see Section 2.2.1 for details. Child health outcomes are measured from the 22nd to 35th year of life, and parental income over 21 years (1st-21st year of each child's life). All income measures are inflation-adjusted, and income ranks, 0-100, are determined within child cohorts. See Section 2 for details on data construction and variables. Standard errors in parentheses; see Tables C.6 to C.12 for point estimates from all specifications.

Figure 5: Intergenerational mobility, fertility

Notes: In this figure, we plot estimates of Specification 1. We consider children born from 1974 to 1988. Same-sex/different-sex attraction is determined by observing cohabiting relationships with at least one financial commitment; see Section 2.2.1 for details. Child fertility outcomes are measured in the 35th year of life, and parental income over 21 years (1st-21st year of each child's life). All income measures are inflation-adjusted, and income ranks, 0-100, are determined within child cohorts. See Section 2 for details on data construction and variables. Standard errors in parentheses; see Tables C.6 to C.12 for point estimates from all specifications.

sive margins among same-sex attracted women at the lower end of the parental income distribution, may contribute to the particularly higher absolute income mobility in these women. As these mobility gaps narrow across the parental income distribution, so does the gap in labour market income between same-sex attracted and different-sex attracted women.

At the extensive margin, the fertility of same-sex attracted men significantly differs from that of different-sex attracted men across the entire parental income distribution, with a 70.5 percentage point (pp.) difference at the intercept. We do not observe higher relative mobility among same-sex attracted men compared to their different-sex attracted counterparts regarding fertility. This is despite the potential need for financial resources to overcome barriers to parenthood for same-sex attracted men. Rather, we find a marginal decrease in the share of same-sex attracted men who parent across the parental income distribution. The small number of same-sex attracted men who do become parents also have fewer children across the entire parental income distribution compared to different-sex attracted men. Compared to different-sex attracted men, the few same-sex attracted fathers are relatively older at the birth of their first child as their parental income increases.

The overall lower fertility among same-sex attracted individuals is not surprising given the legal and practical barriers to having children with a same-sex partner. Such barriers may be more easily overcome by those with fewer financial constraints, potentially explaining the fertility increase of same-sex attracted women across the parental income distribution. These findings align with the higher mean household income but lower fertility among same-sex attracted men compared to same-sex attracted women (as shown in Table 1 above). Our findings suggest that barriers to parenthood for same-sex attracted men are, however, not easily mitigated by financial resources. This is likely because surrogacy is de facto not permitted in Denmark (Tanderup et al., 2024; Indenrigs- og Sundhedsministeriet, 2019), while all women and different-sex couples are eligible for reproductive assistance through both public and private healthcare systems.

4.2.2 Household income

A couple of two women will, on average, experience a lower household income than a couple comprising a man and a woman due to "the gender pay gap". The positive gap in absolute income mobility for same-sex attracted women may, however, mitigate these expected differences in household income. In contrast, couples of two men are expected to have higher household incomes than a couple consisting of a man and a woman, even if same-sex attracted men have lower labour market income than different-sex attracted

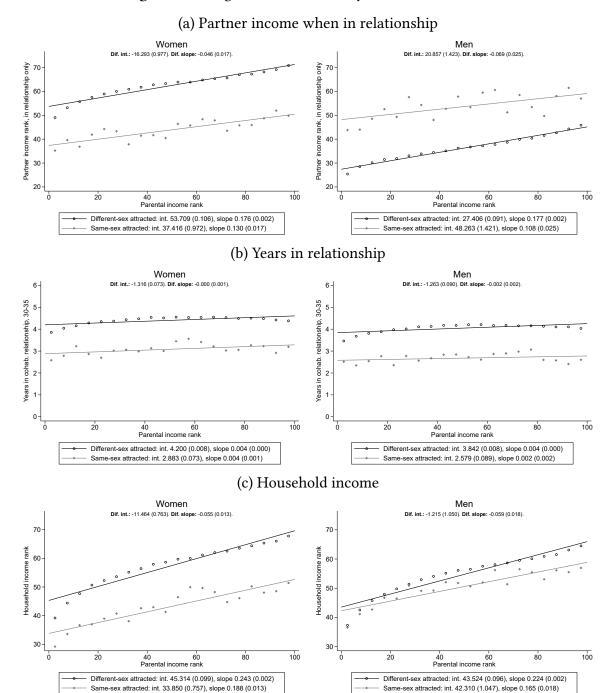

men; on average, same-sex attracted men still earn more than women in the labour market. However, these conclusions depend on the relative matching of same-sex individuals and the number of years spent in cohabiting relationships.

Figure 6, Panel (a), confirms that partner earnings are substantially lower across the parental income distribution for same-sex attracted women compared to their different-sex attracted counterparts; the reverse is true for men. For both same-sex attracted men and women, we observe slightly higher relative mobility (a flatter slope), indicating less assortative matching (defined here as the relationship between parental earnings and partner earnings) compared to different-sex individuals. Nevertheless, the most notable difference lies in absolute mobility, mirroring the trends seen in individual income.

To understand household income dynamics, it is essential to consider relationship dynamics. Figure 6, Panel (b), shows that same-sex attracted men spend less than half of the six years in which potential partner earnings are observed (years 30-35 of life) with a cohabiting partner. Consequently, across the entire parental income distribution, same-sex attracted men spend 1.26 fewer years in relationships than their different-sex attracted counterparts during these six years. Similarly, same-sex attracted women spend 1.32 fewer years in relationships compared to different-sex attracted women, a pattern that is also consistent across the parental income distribution.

In periods outside relationships, partner income is, by definition, zero, which substantially lowers average household income. The influence of time without a partner is evident from Panel (c), where we consider household income relative to parental income, including periods outside relationships. Despite the absolute mobility premium experienced by same-sex attracted women regarding their individual income, the combination of fewer years in relationships and the generally lower earnings of their female partner(s) results in a significant gap in absolute mobility concerning household income, equivalent to -18.24 rank points at the intercept. The gap in household income between same-sex attracted and different-sex attracted women widens as parental income increases due to lower levels of assortative matching. For same-sex attracted men, the combination of lower earnings, longer time spent outside relationships, and less assortative matching means that their household income at the intercept is roughly equal to that of different-sex attracted men, but with a widening gap as parental income rank increases, even though the partners of different-sex attracted men (i.e. women) have considerably lower labour market income.

Figure 6: Intergenerational mobility, household income

Notes: In this figure, we plot estimates of Specification 1. We consider children born from 1974 to 1988. Same-sex/different-sex attraction is determined by observing cohabiting relationships with at least one financial commitment; see Section 2.2.1 for details. Child, child's partner, and child's household income is measured over 6 years (30th-35th year of life), and parental income over 21 years (1st-21st year of each child's life). All income measures are inflation-adjusted, and income ranks, 0-100, are determined within child cohorts. See Section 2 for details on data construction and variables. Standard errors in parentheses; see Tables C.6 to C.12 for point estimates from all specifications.

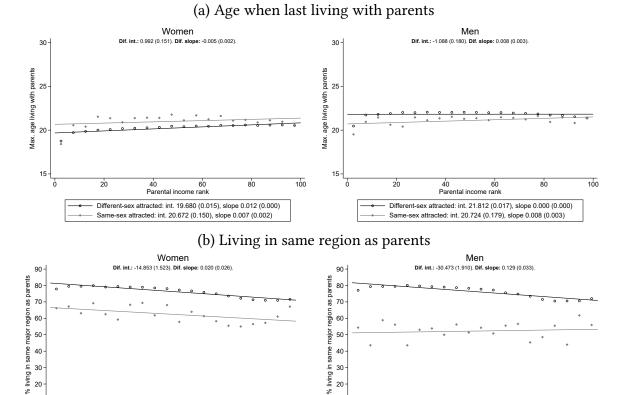

4.3 Potential mechanisms

Across individual and household outcomes, we have found parental income to play a differential role in the lives of their adult children, dependent on sexuality. This may be due to the quality or closeness of the parent-child relationship. To explore this potential mechanism, we approach the parent-child relationship by considering the timing of moving out and proximity to parents after moving out. In Figure 7, Panel (a), we plot the age at which individuals last lived with their parents. We see that same-sex attracted women are older when last living with their parents compared to different-sex attracted women. This holds true across the entire parental income distribution, with a marginally significant difference in relative mobility. For men, we find the opposite trend, as different-sex attracted men generally live longer with their parents and exhibit almost perfect relative mobility (a flat slope), whereas same-sex attracted men tend to live with their parents for shorter periods and demonstrate lower relative mobility. Consequently, the earlier age at which same-sex attracted men move out is particularly pronounced at the lower end of the parental income distribution.

In Figure 7, Panel (b), we consider distance to parents in the children's 35th of life. We find that for women, irrespective of sexuality, a higher parental income rank correlates with a lower likelihood of residing in the same geographical region as their parents. With a substantial difference in absolute mobility, same-sex attracted women are significantly less likely to live near their parents, although they tend to be older when they move out. Different-sex attracted men exhibit a pattern nearly identical to that of different-sex attracted women, whereas same-sex attracted men are the least likely to reside in the same geographical region as their parents. This trend is most pronounced at the lower end of the parental income distribution. For same-sex attracted men specifically, we observe a decrease in the probability of living in the same geographical region as their parents as parental income rank decreases. Overall, this indicates that same-sex attracted men growing up with low-income parents are the most likely to move out early and relocate further from their parents. These dynamics may be attributed to same-sex attracted men preferring greater distance from their parents, as well as low-income parents being less likely to reside near preferred locations.

These results imply a potential mechanism – physical distance from parents – for the sustained gaps in other outcomes, as this may be related to reduced parental support (Hünteler & Mulder, 2020). That same-sex attracted individuals are consistently more likely to locate in other regions than parents also highlight the importance of considering geograph-

To understand the drivers behind the - often stark - differences in mean outcomes between different-sex attracted and same-attracted individuals, we have so far considered three factors: 1) differences in parental income, 2) differences in absolute mobility, and 3) differences in relative mobility. As a next step, we want to assess the relative importance of these three factors. A standard approach to decompose differences in means between

two groups is a Oaxaca-Blinder decomposition. Table 1 and Figure 1 shows that there is little difference in parental income ranks between same-sex and different-sex individuals, i.e. $\bar{y}_{sp} \approx \bar{y}_p \approx y_{p,50}$, where $y_{p,50}$ is the median parental income rank. As such, $\bar{y}_{sp} - \bar{y}_p \approx 0$, and we can simplify the standard Oaxaca-Blinder decomposition to:

$$\underline{\bar{y}_{sc} - \bar{y}_c} \approx \underbrace{\hat{\beta}_s}_{\text{B: Unexplained from absolute mob.}} + \underbrace{\hat{\beta}_{sp}\bar{y}_{p,50}}_{\text{C: Unexplained gap from relative mob.}}$$
(3)

We illustrate this simplified decomposition in Figure 8 by plotting the following two terms:

$$Dif_{p,50} = \frac{B+C}{\bar{y}_c} \times 100 = \frac{\hat{\beta}_s + \hat{\beta}_{sp}\bar{y}_{p,50}}{\bar{y}_c} \times 100, \quad Dif_{abs.} = \frac{B}{\bar{y}_c} \times 100 = \frac{\hat{\beta}_s}{\bar{y}_c} \times 100 \quad (4)$$

Dif $_{p,50}$ gives the percentage difference in means at the median parental income level, including both differences due to absolute and relative mobility (indicated by blue circles in Figure 8). Dif $_{\rm abs.}$ gives the percentage difference in means due to absolute mobility differences (indicated by pink circles in Figure 8). As such, any distance between the pink and blue circles in Figure 8 is due to differences in relative mobility measured at the median (\approx the mean for both groups) parental income.

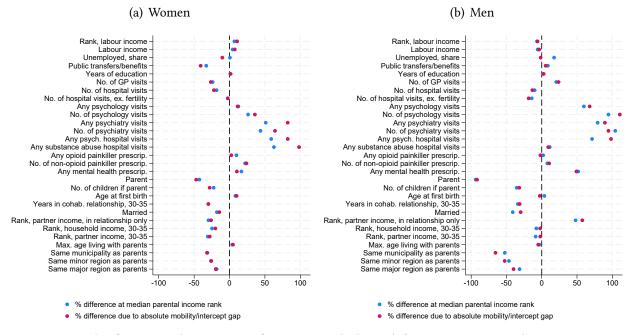

Figure 8 summarises the findings from Sections 3 and 4, but with differences between same-sex and different-sex attracted individuals now expressed in percent relative to the relevant mean for different-sex individuals. In Figure 8, Panel (a) we include the results for women, and in Panel (b), the results for men. As before, we see that same-sex attracted women have higher earnings relative to different-sex attracted women, and that the opposite is true for men. However, Figure 8 also reveals that earnings differences are small relative to differences in health outcomes, partnership dynamics, and location choices. However, the main takeaway from Figure 8 is that for the vast majority of outcomes, differences between same-sex and different-sex individuals are driven by differences in absolute

$$\underline{\bar{y}_{sc} - \bar{y}_c} = \underbrace{\hat{\beta}_s}_{\text{A: Total gap}} + \underbrace{\hat{\beta}_{sp}\bar{y}_{sp}}_{\text{B: Unexplained from absolute mob.}} + \underbrace{\hat{\beta}_{sp}\bar{y}_{sp}}_{\text{D: Explained gap}} + \underbrace{(\bar{y}_{sp} - \bar{y}_p)\hat{\beta}_p}_{\text{D: Explained gap}} \tag{2}$$

where \bar{y}_{sc} and \bar{y}_c denotes the mean income ranks same-sex attracted and different-sex attracted individuals, respectively. Similarly, \bar{y}_{sp} and \bar{y}_p are the mean income ranks of the parents of each group. $\hat{\beta}_s$, $\hat{\beta}_{sp}$, and $\hat{\beta}_p$ are the coefficients estimated from Specification 1, where $\hat{\beta}_s$ is the difference in intercept/absolute mobility between same-sex and different-sex attracted individuals, and $\hat{\beta}_{sp}$ the difference in slope on parental income/relative mobility, and $\hat{\beta}_p$ the slope/relative mobility for different-sex attracted individuals. Following Fortin et al. (2011), we refer to the sum of B and C as the "unexplained" part of the differences in means (that is, unexplained by differences in parental income ranks between the two groups). The term D yields the "explained" gap (that is, explained by differences in parental income ranks between the two groups).

¹¹This methods was developed in Oaxaca (1973) and Blinder (1973), and is described in Fortin et al. (2011). We follow the terminology of Fortin et al. (2011). A detailed Oaxaca-Blinder decomposition yields the following:

Notes: In this figure, we plot estimates of Equation 4 which are differences in outcomes between same-sex and different-sex attracted individuals. Blue circles give the percentage difference in means at the median parental income level, including both differences due to absolute and relative mobility. Pink circles give the percentage difference in means due to absolute mobility differences. We consider children born from 1974 to 1988. Same-sex/different-sex attraction is determined by observing cohabiting relationships with at least one financial commitment; see Section 2.2.1 for details. Child, child's partner, and child's household income is measured over 6 years (30th-35th year of life). Child education, fertility outcomes, as well as child and parent region of residence are measured in the 35th year of life of each child. Child health outcomes are measured from the 22nd to 35th year of life. Parental income is measured over 21 years (1st-21st year of each child's life). All income measures are inflation-adjusted, and income ranks, 0-100, are determined within child cohorts. See Section 2 for details on data construction and variables.

mobility (i.e. the distances between the pink and blue circles tend to be small). This conclusion is important as it highlights that (dis)advantage in outcomes experienced by same-sex attracted individuals is largely similar independently of parental income. In other words, higher parental income tend not to alleviate the (dis)advantage experienced by same-sex attracted individuals. The main exception to this general conclusion is in psychiatric and substance abuse treatment, especially for women, where higher relative mobility for same-sex attracted individuals (a flatter slope in health-rank relationship) reduce the difference in outcomes between same-sex and different-sex attracted individuals at the median parental income rank.

As we identify differences in absolute mobility as the primary driver of differences in means, this will be the focus in the sections that follow, including in specifications controlling for selection through sibling FEs, as well as in heterogeneity analyses by regions and cohorts.

6 Selection and sibling comparisons

Selection poses a key concern when studying sexual minorities, as researchers only observe those who disclose their sexuality.¹² Whilst our sample shows similar parental income backgrounds between same-sex and different-sex attracted individuals (see Figure 1 and Table 1), same-sex attracted individuals who choose to live in same-sex relationships may differ in unobservable parental characteristics from those who do not. This could confound the causal effect of sexuality with selection into disclosure. For instance, same-sex attracted individuals in relationships might have particularly supportive parents who both facilitate disclosure and provide educational or health support. Danish administrative data's long time span and rich family information allow us to control for such unobserved heterogeneity by comparing siblings with identical parental backgrounds but different sexuality. Unlike most intergenerational mobility studies (Chetty et al., 2020; Boustan et al., 2025), where group identifiers (e.g., ethnicity, parental migration status) are fixed within families, sexuality varies between siblings, enabling sibling comparisons.

When including sibling FEs, we want all sibling sets in our estimation sample, including those of different sexes. Therefore, we cannot estimate specifications separately for daughters and sons as in Specification 1. We instead expand our specification to include sex interaction terms. We vary the reference group between sons and daughters to maintain comparability with Specification 1. Since parental income coefficients are only identified from differences between siblings, and parental income ranks remain stable across siblings ($R^2 = 0.97$ when regressing parental income rank on sibling FEs), we exclude parental income controls in our preferred specification:¹³

$$y_{if,c} = \beta_f + \beta_s \operatorname{same_sex}_i + \beta_g \operatorname{sex}_i + \beta_{sg} \operatorname{sex}_i \cdot \operatorname{same_sex}_i + \varepsilon_{if}$$
 (6)

where notation follows Specification 1, with subscript f indicating family-level variation, β_f is sibling FEs, and sex_i indicates whether individual i's sex differs from the reference group. Sibling FEs control non-parametrically for time-invariant parental characteristics, so Specification 6 compares absolute mobility (β_s) between same-sex and different-sex at-

$$y_{if,c} = \beta_f + \beta_p y_{i,p} + \beta_s \text{same_sex}_i + \beta_{sp} y_{i,p} \cdot \text{same_sex}_i + \beta_g \text{sex}_i + \beta_{pg} \text{sex}_i \cdot y_{i,p} + \beta_{sq} \text{sex}_i \cdot \text{same_sex}_i + \beta_{spq} \text{sex}_i \cdot \text{same_sex}_i \cdot y_{i,p} + \varepsilon_{if}$$
(5)

 $^{^{12}} Individuals$ can disclose sexuality directly in surveys, through marriage/co-parenting with same-sex partners in administrative studies, or – as in this paper – through same-sex relationships with joint financial commitments.

¹³The specification also includes controls for year-of-birth FEs and their interaction with sex, but these are not shown here for brevity. The full specification with sibling FEs and parental income ranks is:

tracted individuals. Since we exclude relative mobility terms, β_s represents the average mobility difference across all income ranks, approximating the causal effect of sexuality on early adulthood outcomes. When relative mobility differences are small – as Figure 8 shows for most outcomes – absolute mobility equals average mobility, enabling comparison between sibling FE estimates and absolute mobility to assess selection bias. This analysis requires each child to have at least one sibling in our sample (57% of the main sample). To interpret sibling FE estimates causally, we assume that unobserved parental heterogeneity affecting relationship choices does not correlate with our outcomes. Sibling FEs largely control for genetic and family environment variation (Ronda et al., 2022). While genetics may relate to sexuality, current evidence indicates weak associations (Ganna et al., 2019). If sibling FE estimates closely align with absolute mobility estimates, this suggests that unobserved parental characteristics play a minimal role in disclosure selection.

Tables C.6 to C.12 in Appendix C present estimates from: 1) our main specification, as shown in Figures 2 to 7; 2) specifications with cohort FEs; 3) Estimates from our main specification on the 57% sibling subsample; 4) Specification 5 estimated on the sibling sample; and 5) Specification 6 estimated on the sibling sample. We summarise these results in Figure 9, comparing absolute mobility differences (β_s) from Specification 1 with sibling FEs estimates from Specification 6 for four key outcomes. Panel (a) shows that in terms of income rank, same-sex attracted women experience higher absolute mobility and positive causal effects (\approx 4.5 rank points) across both specifications. Same-sex attracted men show comparable negative effects in both specifications, with similar precision. Panel (b) shows slightly larger estimated gaps for women's mental health prescription use with sibling FEs (0.04 vs. 0.03 pp.), though the difference is not statistically significant. Results are very similar across specifications for men. Panel (c) demonstrates that lower fertility rates amongst same-sex attracted individuals are not driven by unobserved parental heterogeneity. Panel (d) shows similar estimates for proximity to parents, with slightly smaller sibling FEs estimates for same-sex attracted men.

Our estimates, which control solely for parental income, closely match those that account non-parametrically for family background through sibling FEs. The sibling FE specification yields estimates approaching causal effects of sexuality on early adulthood outcomes, suggesting that our results are not sensitive to selection into disclosure beyond what

 $^{^{14}}$ This specification assumes that the sibling fixed effect, β_f , is not sex specific. As such, we assume that a daughter and a son of the same mother will experience a similar effect of their parental background compared to peers of the same sex. An alternative would be to focus on sets of siblings of the same sex to estimate brother and sister FEs separately, but this would substantially limit our sample size and disproportionally include children with three or more siblings.

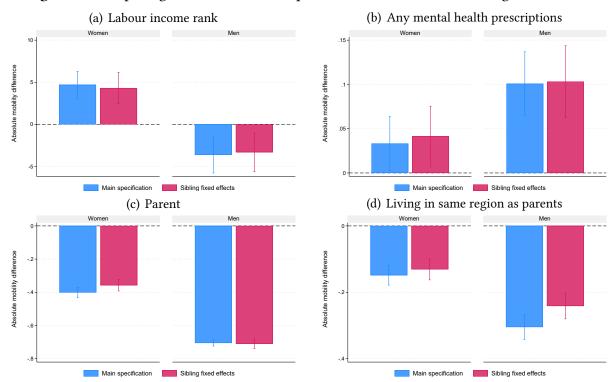

Figure 9: Comparing results from main specification to those with sibling fixed effects

Notes: In this figure, we plot estimates of β_s from Specification 1 (blue bars) and Specification 6 (pink bars) respectively. We consider children born from 1974 to 1988. Same-sex/different-sex attraction is determined by observing cohabiting relationships with at least one financial commitment; see Section 2.2.1 for details. See Section 2 for details on data construction and variables. Child income is measured over 6 years (30th-35th year of life). Child health outcomes are measured from the 22nd to 35th year of life. Child fertility outcomes, as well as child and parent region of residence are measured in the 35th year of life of each child. Parental income is measured over 21 years (1st-21st year of each child's life). See Tables C.6 to C.12 for point estimates from all specifications. 95%-level confidence intervals indicated, based on standard errors clustered at the sibling level.

parental income explains. This robustness across specifications with and without sibling FEs is pertinent in many other contexts, as alternative data sources on the outcomes of sexual minorities typically lack data on siblings and their outcomes, rendering a fixed-effects approach infeasible.

7 Heterogeneity and extensions

In Section 4, we report comparisons between all our observed same-sex attracted and different-sex attracted individuals. However, to better understand the underlying dynamics behind our results and for policy purposes, the potential heterogeneity *within* the group of same-sex attracted individuals is also crucial to understand. In the following, we explore heterogeneity across two key dimensions: childhood regions and cohorts.

Same-sex individuals (men, in particular) remain more concentrated in metropolitan areas than different-sex attracted individuals (Wimark & Fortes De Lena, 2022). Therefore,

we may expect that same-sex attracted individuals growing up in metropolitan areas are less likely to face certain minority stressors (Meyer, 1995), which may affect their outcomes in terms of earnings, health, and relationships. In addition, our data consist of 15 cohorts (born 1974-1988), allowing us to consider if differences in mobility parameters between same-sex attracted and different-sex attracted individuals change over time as Denmark (at the same time as many other OECD countries) have changed policies to become more inclusive of same-sex attracted individuals (see e.g. Evertsson et al., 2020). Informed by the discussion in Section 5, we focus primarily on differences in intercepts, i.e. absolute mobility, in the following sections. In addition, we focus on three representative outcomes: labour income rank, any mental health prescriptions, and finally, whether individuals are parents. Results for the remaining outcomes are included in Appendix D.

Finally, in Section 7.3, we extend our analysis of income differences between samesex attracted and different-sex attracted individuals by also considering variation in child income ranks conditional on parental income rank. This approach complements our previous analyses since differences in conditional mean child income ranks between same-sex attracted and different-sex attracted individuals do not provide insight into the dispersion of child income.

7.1 Regional differences

An extensive literature documents the importance of childhood home region for economic outcomes (for results from the US, see e.g. Chetty et al. 2014; for results from Denmark, see e.g. Eriksen & Munk 2020). Beyond economic factors, regions may also differ in their social norms and attitudes, e.g., metropolitan areas may exhibit values that correlate with greater acceptance and less discrimination toward sexual minorities. We undertake region-specific analyses to examine differences in absolute intergenerational mobility between same-sex attracted and different-sex attracted individuals based on their childhood region. Our analyses lend some support to the "protective" nature of metropolitan areas, especially for same-sex attracted men. For example, same-sex attracted men who grew up in the capital do not experience significantly different absolute mobility in mental health outcomes compared to different-sex attracted men. We fully present and discuss our region-specific analyses in Appendix D.1.

7.2 Cohort differences

To consider differences in mobility parameters over time – that is, across cohorts – we first divide our sample of children into three groups based on their birth year, considering separately those born in 1974-1978, 1979-1983, and 1984-1988. Thus, each cohort group

contains children born across five years, allowing us to consider changes in mobility parameters over 15 birth years. Next, we estimate Specification 1 separately for each of these three cohort groups. We show a selection of cohort-level results in Figure 10 which plots, β_s , i.e. the difference in intercept/absolute mobility between same-sex attracted and different-sex attracted individuals, for each cohort group in black circles. The black dashed line shows the mean estimate for aggregate sample (and its 95%-confidence interval in shaded grey). Cohort-level analyses for the remaining outcomes are visualised in in Figure D.5

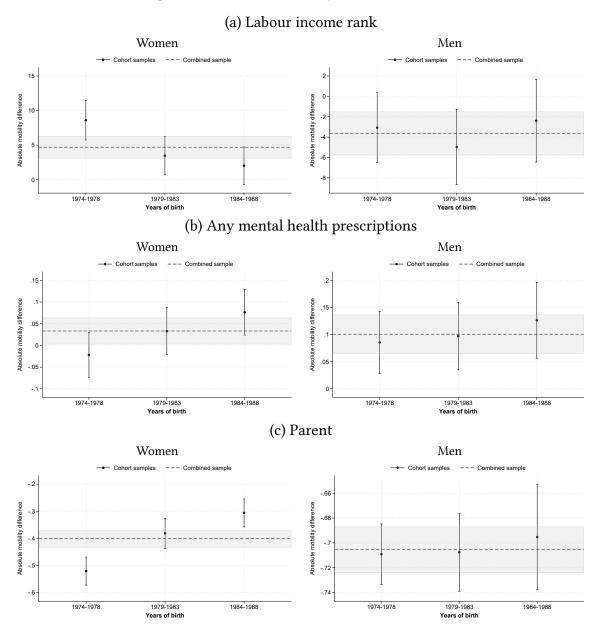

Panel (a) of Figure 10 shows little development in absolute mobility gaps in earnings between same-sex attracted and different-sex attracted men over time, suggesting a persistent "gay penalty" for men across cohorts. For women, however, the absolute mobility gap in earnings (favouring same-sex attracted women) appears to be narrowing in younger cohorts, suggesting that the "lesbian premium" is shrinking. In contrast, Panel (b) indicates that the gap in mental health prescriptions is increasing over time. As such, the heightened risk of mental health issues in same-sex attracted individuals relative to their different-sex attracted peers appears to be increasing over time. This highlights the need for additional mental health-promoting policies targeted at sexual minority individuals.

Panels (c) shows the fertility gap between same-sex attracted and different-sex attracted women shrinking in younger cohorts, whereas the male gap largely persists. This aligns with the gradual removal of legal barriers to parenthood for women in same-sex couples in Denmark (Evertsson et al., 2020). The increase in same-sex attracted women's fertility is likely to be part of the explanation for the convergence of same-sex attracted and different-sex attracted women's income, as same-sex attracted women increasingly will be affected by the "child penalty" (Andresen & Nix, 2022; Kleven et al., 2019). This is likely to occur in conjunction with the similar convergence of educational attainment between same-sex attracted and different-sex attracted women in younger cohorts (as shown in Figure D.5).

7.3 Income variation

As in many existing analyses of intergenerational rank-rank relationships between child and parent income, we consider the sum of income in a given age range for both parents and children in Section 4.1.1. In Appendix D.3, we instead explore how variation in child income rank evolves across the parental income distribution differentially for same-sex and different-sex attracted individuals. We find that, conditional on parental income, same-sex attracted individuals do not only experience different mean levels in income (higher for women, lower for men), but their income distribution also have a larger variance. Furthermore, we show that, unconditional on parental income, population-level income distribu-

Figure 10: Absolute mobility, cohort differences

Notes: In this figure, we plot estimates of β_s from Specification 1, but dividing our sample of children into three groups based on their year of birth. We consider children born in 1974-1978, 1979-1983, and 1984-1988. Same-sex/different-sex attraction is determined by observing cohabiting relationships with at least one financial commitment; see Section 2.2.1 for details. Child income is measured over 6 years (30th-35th year of life). Child health outcomes are measured from the 22nd to 35th year of life. Child fertility outcomes are measured in the 35th year of life of each child. Parental income is measured over 21 years (1st-21st year of each child's life). All income measures are inflation-adjusted, and income ranks, 0-100, are determined within child cohorts. See Section 2 for details on data construction and variables. 95%-level confidence intervals indicated, based on standard errors clustered at the sibling level.

tions of both same-attracted women and men are more dispersed, with underrepresentation at the middle of the sex-specific income distributions.

These analyses provide suggestive evidence for why we observe relatively modest mean income rank gaps between same-sex attracted and different-sex attracted individuals, despite larger differences in other areas, such as mental health outcomes. That is, the high income of some individuals conceals the low income of others when only considering differences in means and rank-rank regressions. These findings also indicate that future research on same-sex attracted individuals should examine both means and variance in income, leaving the causal identification of factors driving within-group inequalities as an interesting avenue for further research.

8 Conclusions

Research on sexual minorities has long been held back by the limited available data on sexuality in combination with comprehensive information on relevant outcomes. We develop a new way to identify both same-sex and different-sex attracted individuals in population-wide administrative data from Denmark using joint financial commitments in couples. As such, we alleviate concerns about selection/reporting bias in surveys on sexual minorities, and we avoid relying only on measuring sexuality through relatively rare outcomes amongst same-sex couples, such as marriage and co-parenthood. Another primary advantage of our data and our measure of sexuality is that we can link observed sexuality to both the outcomes of adult children and to their parents' income during the childhood of the children in question. Thus, the richness, the long time span, and the large sample of same-sex attracted couples of the Danish administrative data allow us to analyse differences in the relationship between parents' and adult children's income, i.e. intergenerational mobility, by the adult children's sexuality.

We start by documenting that same-sex and different-sex attracted individuals are equally represented along the parental income distribution. That is, same-sex attraction is not meaningfully related to parental income. This result is not trivial: as higher educational attainment and income are associated with more supportive attitudes towards same-sex attracted individuals (Slenders et al., 2014; La Roi & Mandemakers, 2018), one could imagine that openness about sexuality, and thus, the probability of being observed in a same-sex couple, would be related to parental income.

We continue to show that across the entire parental income distribution, same-sex attracted men experience inferior labour market outcomes when compared to different-sex attracted men, indicating that parental financial resources do not mitigate the labour mar-

ket penalties endured by same-sex attracted men. To a large extent, this picture is reversed for women, where same-sex attracted women have higher earnings and lower rates of unemployment across the entire parental income distribution. That is, the "gay/lesbian penalty/premium" is not dependent on parental income. We believe that this finding is new to the literature where differences in income by sexuality have not been considered in the context of parental income, most likely due to the lack of appropriate data.

We also consider differences in education, fertility, health, household composition, and location choices by sexuality and by parental income. In doing so, we document large and persistent gaps across the parental income distribution for many of the outcomes, but not always in the direction the relevant income gaps would suggest. For example, we find consistently higher levels of education, lower fertility rates, lower numbers of hospital visits (also excluding fertility-related visits), and more regional mobility across the parental income distribution for both same-sex attracted women and men, which should predict higher earnings. These factors are likely to contribute to the "lesbian premium", but they do not help us to understand the drivers of the "gay penalty", which both persist throughout the parental income distribution. In contrast, we find substantially higher levels of mental health conditions and lower levels of cohabitation among same-sex attracted individuals. The higher prevalence of mental health treatments among same-sex attracted individuals is evident across the entire parental income distribution, but severe mental health conditions (observed as treatment in psychiatric hospitals) are particularly prevalent at the bottom of the parental income distribution for same-sex attracted individuals. Together, these findings suggest that higher parental income does not mitigate the mental health challenges faced by sexual minorities, with the exception of the most severe types of illness. We find that same-sex attracted individuals are more likely to reside in regions away from their parents across the parental income distribution, implying a potential mechanism – physical distance from parents – for the sustained gaps in outcomes.

We consider that our results may be affected by heterogeneity in parental characteristics beyond parental income. Beyond gender, other research that estimate differences in intergenerational mobility by demographics groups typically consider demographic characteristics that are fixed within families, for example, race (Chetty et al., 2020) and immigration status (Abramitzky et al., 2021; Boustan et al., 2025; Jensen & Manning, 2025). In our setting, we can exploit that sexuality often varies among siblings, allowing us to control non-parametrically for additional parental heterogeneity (both observed and unobserved) by including sibling FEs in our model. We find that our results are robust to controlling for

additional parental heterogeneity when including sibling FEs. Controlling for sibling FEs brings us closer to causal estimates of the effect of sexuality on outcomes in early adulthood.

Finally, we find little regional and cohort variation in intergenerational relationships, but with three notable exceptions: First, same-sex attracted women from more recent cohorts have higher fertility rates. This indicates that women in more recent cohorts benefit from improved access to fertility services for single and same-sex partnered women. Second, in line with increased fertility, the higher income amongst same-sex attracted women converge towards zero for more recent cohorts, potentially because they are increasingly affected by the "child penalty." Finally, we find a substantially higher risk of mental health issues in same-sex attracted individuals – a risk that, to a large extent, persists across the entire parental income distribution. This difference in risk between same-sex attracted and different-sex attracted individuals *increases* in younger cohorts.

Together, our results suggest that the disadvantages faced by same-sex attracted individuals are mitigated only to a limited extent by high parental income. The lack of mitigation of outcome gaps between same-sex and different-sex attracted individuals by parental resources and their correlates suggests that non-pecuniary factors significantly contribute to differences in lived experiences. The higher prevalence of mental health conditions among same-sex attracted individuals across the parental income distribution further indicates that cultural factors, such as discrimination, may not be alleviated by parental resources. Our results also imply that intergenerational mobility depends not only on factors shared by siblings but also on innate individual characteristics, such as sexuality, in addition to gender. Factors shared by siblings as well as these innate individual characteristics may be targets for policymakers aiming to improve social mobility, and our results carry significant policy implications.

The increasing difference in the risk of mental health issues in younger cohorts illustrates that the unique challenges faced by same-sex attracted individuals remain far from adequately addressed by policy-makers, and that further initiatives are necessary if the population-level mental health crisis currently endured by same-sex attracted individuals is not to worsen. Our results on fertility patterns – documenting that almost no same-sex attracted men, even those from the most financially resourceful backgrounds, have children – are illustrative of the legal barriers that same-sex attracted men face to parenthood. This highlights the need for policies that facilitate, rather than hinder, family formation for same-sex attracted men who want children. Finally, the fact that the pay penalty for same-sex attracted men exists and persists across the entire income distribution, despite

their consistently higher educational levels, illustrates that sexuality-specific barriers in the labour market – whether strictly discriminatory or normative – are not isolated to subsamples of individuals growing up under certain financial conditions, highlighting the need for wide-spread change.

ONLINE APPENDIX:

Intergenerational Mobility by Sexuality

A Data details

A.1 Validation of couple's measure

We undertake a series of analyses to validate our new couples measure. First, we show that financial commitment works as a couples measure among married couples and couples with children. Using full population data on everyone aged 35 from 2003 to 2022, in Table A.1, we observe that financial commitments are highly prevalent among cohabiting couples who are either married or parents of the same child, regardless of the sex composition of the couple. This indicates that same-sex and different-sex couples, as observed through more conservative methods — specifically, marriage and co-parenthood — are equally likely to share financial responsibilities. Since we observe that joint financial commitments are widespread among both same-sex and different-sex couples, joint financial commitments are likely to effectively capture both same-sex and different-sex couples, even in the absence of children and marriage. We use this insight as we proceed to use joint financial commitments to also capture cohabitating couples, including those who are not married or co-parents. The specific types of commitments are detailed in Table A.2. We find that while the rates of financial commitments are comparable between same-sex attracted and different-sex attracted individuals, the rates of marriage and joint parenthood are significantly lower among same-sex attracted individuals. This further emphasises the advantage of using financial data to identify cohabiting couples across varying sexualities.

Table A.1: Married or co-parenting cohabiting couples who share financial responsibilities

Financial match	0.933	0.915	0.882	0.928
	(0.000339)	(0.000344)	(0.00546)	(0.00626)
N	542,948	659,257	3,486	1,706

Notes: This table reports the share of married and co-parenting cohabiting couples who share at least one financial responsibility when observed at age 35, from 2003 to 2022. Financial responsibilities include joint owned properties, joint credit accounts, joint debit accounts, and joint mortgages; see Section 2.2.1 for further details. Standard errors in parentheses.

N 3,688,402 25,866 3,986	N	3,688,402	25,866	3,986

Notes: This table reports the share of couples with a given commitment from 2003 to 2022. Different sex / same sex/ both sexes attraction is determined by observing cohabiting relationships with at least one of the listed commitments between 2003 to 2022 with partner(s) of the relevant sex; see Section 2.2.1 for details. Standard errors in parentheses.

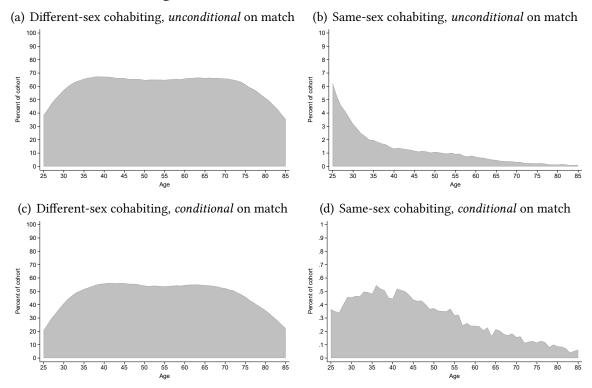

Next, we show that the observation of joint financial commitments allow us to distinguish same-sex and different-sex couples from two-person households made up by housemates. In Figure A.1, we show the percentage of age cohorts that cohabit, by sex composition, and with and without shared financial responsibilities. Panel (a) visualises the percentages of each cohort that cohabit with someone of a different sex; Panel (b) visualises the percentages of each cohort that cohabit with someone of the same sex; Panel (c) visualises the percentages of each cohort that cohabit with someone of a different sex, conditional on shared financial responsibilities; and Panel (d) visualises the percentages of each cohort that cohabit with someone of the same sex, conditional on shared financial responsibilities. In Panel (b), we see that unconditional on shared financial responsibilities, more than 6% of individuals at age 25 cohabit with someone of the same sex. This share decreases steeply across the age distribution until age 35, after which the curve flattens. This indicates that using cohabitation alone to identify couples would include a large num-

ber of non-partnering housemates; a phenomena that decreases with age. In Panel (d), we condition on cohabitation and a joint financial commitment, resulting in a significant drop in the number of identified individuals in same-sex cohabitation (from around 2% to 0.5% at age 35). We also see the age distribution peaking around age 35-45, as we would expect if correctly identifying couples, rather than housemates. Comparing Panels (c) and (d), we see similar age patterns for different-sex couples and same-sex couples until age 50, after which the proportion of individuals in same-sex relationships decreases steadily. This mirrors the consistent finding that younger cohorts are more likely to identify as non-heterosexual (e.g., ONS, 2023; Gallup, 2025) and the historically lower life-expectancy for same-sex attracted individuals (Frisch & Simonsen, 2013; Hogg et al., 1997). Comparing Panels (a) and (c), we see a relatively smaller drop in the observed percentages in different-sex cohabitation when conditioning on shared financial responsibilities (from just more than 60% to around 50% at age 35), reflecting that proportionately fewer different-sex cohabitations occur without shared financial responsibilities compared to same-sex cohabitations. Hence, more often than not, same-sex cohabitation is likely to reflect housemates, whereas different-sex cohabitation more often than not reflects different-sex couples, highlighting the importance of distinguishing these groups.

To further verify that we are indeed observing partnering couples when conditioning on cohabitation *and* a joint financial commitment, we consider relationship trajectories. If the same-sex couples observed with joint financial commitments are in fact housemates, we would expect a large number of them to sort into different-sex relationships over time, whereas only a small fraction would sort into other types of same-sex relationships (i.e., same-sex marriage and/or parenting with a person of the same sex). If we reliably capture cohabiting same-sex couples, we would expect to see that the majority remain in same-sex relationships over time. We show trajectories for same-sex attracted men and women separately in Figure A.2.

Five years after a same-sex cohabiting relationship is first observed, more than 70% of women and 60% of men are still in a same-sex relationship. For both men and women, the majority of these relationships have transferred into same-sex marriage or parenting with a same-sex partner. More men than women are not in observable relationship five years after observed same-sex cohabitation, indicating shorter relationship durations among same-sex attracted men compared to same-sex attached women (this finding is in line with previous findings by, e.g., Lau, 2012). A small proportion have sorted into a difference-sex marriage or parenting with a different-sex partner, and even fewer are in cohabiting relationship

Figure A.1: Cohabitation and financial match

Notes: This figure plots the share of individuals in cohabiting two-person households across age. Panels (a) and (b) show the share unconditional on financial commitments. Panels (c) and (d) condition on at least one shared financial responsibility. Panels to left consider different-sex cohabitants, panels to the right same-sex cohabitants. We consider the full Danish population aged 25-85 in 2019.

(a) Women (b) Men .8 .8 SSC: Married/co-parents .6 .6 SSC: Cohabitation Share DSC: Married/co-parents DSC: Cohabitation No cohabiting partner .2 .2 0 2

Figure A.2: Trajectories of same-sex cohabiting couples

Notes: This figure plots the couple trajectories of individuals who cohabit and share financial responsibilities with a person of the same sex in year 0. SSC = same-sex couple, DSC = different-sex couple. We consider all cohabitation spells with shared financial responsibilities starting from 2004 to 2017. We use data from 2003 to determine if a spell starts in 2004. We use data till 2022 to determine the outcomes of those in spells in 2017 or earlier. For equivalent trajectories for those starting different-sex couples, see Figure A.3.

(i.e. cohabiting and shared financial commitments) with a different-sex partner. This small fraction of people moving from same-sex to different-sex partnerships reflect that part of the population have partners of different sexes throughout the life cycle. The small fraction of transfers from same-sex relationships to different-sex relationships rules out any widespread misclassification when we condition on cohabitation *and* joint financial commitments. We find similar results for different-sex couples; see Figure A.3 for visualisations.

(a) Women (b) Men .8 8. SSC: Married/co-parents SSC: Cohabitation DSC: Married/co-parents DSC: Cohabitation No cohabiting partner .2 .2 2 3 2 Years after cohabitation start Years after cohabitation start

Figure A.3: Trajectories of different-sex cohabiting couples

Notes: This figure plots the couple trajectories of individuals who cohabit and share financial responsibilities with a person of the different sex in year 0. SSC = same-sex couple, DSC = different-sex couple. We consider all cohabitation spells with shared financial responsibilities starting from 2004 to 2017. We use data from 2003 to determine if a spell starts in 2004. We use data till 2022 to determine the outcomes of those in spells in 2017 or earlier. For equivalent trajectories for those starting same-sex couples, see Figure A.2.

As a final validation of our couples measure, we consider contraceptive use among women in different types of cohabiting households. We expect to find that women in same-sex couples are less likely to use contraceptives than women in different-sex relationships, as they are less likely to engage in sexual activity that can lead to pregnancy. If our strategy, relying on joint financial commitments, effectively captures couples and not housemates, we should expect women in same-sex relationships identified through joint financial commitments to be equally likely to use contraceptives as women in same-sex marriage or same-sex shared parenthood. We make this comparison using an OLS regression, including age FEs as controls. As shown in Table A.3, we find that women in same-sex relationships are 19.5-23.1 percent less likely to use contraceptives (this is in line with previous findings, e.g. Ela & Budnick, 2017). We find no statistically significant differences in contraceptive use between women in same-sex relationships based on the route of

¹⁵We only use women's contraceptives as these are recorded in population-wide data on medical prescriptions. Female contraceptions require prescriptions (e.g. pills and IUD's).

1100 - 1, 550 Equality	0.103

Notes: This table reports take-up of any medical contraceptive in 2019 by women aged 26-40, based on observed sexuality and type of couple information. "Single, with roomie" refer to those in two-person households with no shared financial responsibility. The reference group / omitted category is women with no housemate/cohabiting partner. The couple categories are mutually exclusively. If a couple are both married and co-parents, they are categorised as co-parents. A couple is only categorised as identified through a "Financial commitment" if they are neither married nor co-parents. Age FEs are included as controls. Standard errors in parentheses, * p < 0.05, ** p < 0.01, *** p < 0.001

identification (marriage vs. joint child vs. cohabitation with joint financial commitment). Again, these findings support that we effectively capture couples and not housemates when conditioning on both cohabiting *and* a financial commitment. Finally, notice that the rate of contraceptive use varies substantially between women in the various types of different-sex relationships. This reflects that contraceptive use decreases when couples plan pregnancies.

Notes: This table reports means of outcomes by sex and sexuality. Numbers in parentheses state the years in which an outcome is observed, i.e., 30-35 refers to the 30th-35th years of life. For parental outcomes, numbers in parentheses refer to child years of life. Max years living with parents refers to the year last observed living in a household with parents until year 35. See Section 2 for further details on variables and data construction. * p < 0.1, *** p < 0.05, **** p < 0.01

Notes: In this table, we report estimates of Specification 1 in Column 1. Column 2 adds cohort FEs. Column 3 consider only those with siblings in the sample. Column 4 includes estimates of Specification 5, and Column 5 estimates of Specification 6. We consider children born from 1974 to 1988. Same-sex/different-sex attraction is determined by observing cohabiting relationships with at least one financial commitment; see Section 2.2.1 for details. Child income is measured over 6 years (30th-35th year of life), child education in the 35th year of life of each child. Parental income is measured over 21 years (1st-21st year of each child's life). All income measures are inflation-adjusted, and income ranks, 0-100, are determined within child cohorts. See Section 2 for details on data construction and variables. Standard errors clustered at the sibling level, * p < 0.05, ** p < 0.01, *** p < 0.001

Notes: In this table, we report estimates of Specification 1 in Column 1. Column 2 adds cohort FEs. Column 3 consider only those with siblings in the sample. Column 4 includes estimates of Specification 5, and Column 5 estimates of Specification 6. We consider children born from 1974 to 1988. Same-sex/different-sex attraction is determined by observing cohabiting relationships with at least one financial commitment; see Section 2.2.1 for details. Child health outcomes are measured from the 22nd to 35th year of life. Parental income is measured over 21 years (1st-21st year of each child's life). All income measures are inflation-adjusted, and income ranks, 0-100, are determined within child cohorts. See Section 2 for details on data construction and variables. Standard errors clustered at the sibling level, * p < 0.05, ** p < 0.01, *** p < 0.001

Notes: In this table, we report estimates of Specification 1 in Column 1. Column 2 adds cohort FEs. Column 3 consider only those with siblings in the sample. Column 4 includes estimates of Specification 5, and Column 5 estimates of Specification 6. We consider children born from 1974 to 1988. Same-sex/different-sex attraction is determined by observing cohabiting relationships with at least one financial commitment; see Section 2.2.1 for details. Child region, marital status, and fertility outcomes are measured in the 35th year of life of each child. Parental income is measured over 21 years (1st-21st year of each child's life). All income measures are inflation-adjusted, and income ranks, 0-100, are determined within child cohorts. See Section 2 for details on data construction and variables. Standard errors clustered at the sibling level, * p < 0.05, ** p < 0.01, *** p < 0.001

Notes: In this table, we report estimates of Specification 1 in Column 1. Column 2 adds cohort FEs. Column 3 consider only those with siblings in the sample. Column 4 includes estimates of Specification 5, and Column 5 estimates of Specification 6. We consider children born from 1974 to 1988. Same-sex/different-sex attraction is determined by observing cohabiting relationships with at least one financial commitment; see Section 2.2.1 for details. Child, child's partner, and child's household income is measured over 6 years (30th-35th year of life). Parental income is measured over 21 years (1st-21st year of each child's life). All income measures are inflation-adjusted, and income ranks, 0-100, are determined within child cohorts. See Section 2 for details on data construction and variables. Standard errors clustered at the sibling level, * p < 0.05, ** p < 0.01, *** p < 0.01

Sibling FEs											

Notes: In this table, we report estimates of Specification 1 in Column 1. Column 2 adds cohort FEs. Column 3 consider only those with siblings in the sample. Column 4 includes estimates of Specification 5, and Column 5 estimates of Specification 6. We consider children born from 1974 to 1988. Same-sex/different-sex attraction is determined by observing cohabiting relationships with at least one financial commitment; see Section 2.2.1 for details. Child and parent region of residence are measured in the 35th year of life of each child. Parental income is measured over 21 years (1st-21st year of each child's life). All income measures are inflation-adjusted, and income ranks, 0-100, are determined within child cohorts. See Section 2 for details on data construction and variables. Standard errors clustered at the sibling level, * p < 0.05, ** p < 0.01, *** p < 0.001

D Heterogeneity and extensions

D.1 Regional variation

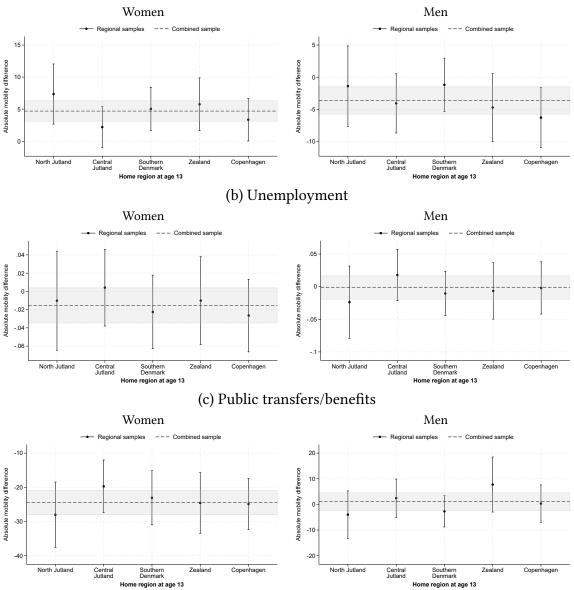

Denmark consists of five major regions (NUTS-2 level): North Jutland, Central Jutland, Southern Denmark, Zealand, and Copenhagen. Copenhagen is the capital of Denmark and represents the only region with a major metropolis. We start our regional analysis by dividing our sample of children into five groups based on the region in which they lived at age 13, that is, before the children themselves would be able to choose where to live. Next, we estimate Specification 1 separately for each of these five groups. Figure D.4 plots, β_s , i.e. the difference in intercept/absolute mobility between same-sex attracted and different-sex attracted individuals, for each region in black circles. In addition, the black dashed line shows the mean estimate for aggregate sample (and its 95%-confidence interval in shaded grey).

Generally, our region-level estimates hover close around the mean estimate from the aggregate sample. However, a few interesting patterns are worth highlighting. In Panel (a), we consider labour income ranks. For same-sex attracted women, we consistently see positive and generally statistically significant gaps in absolute mobility across regions. For men, we see that the negative gap in absolute mobility is slightly larger for those who grew up in Copenhagen. When considering mental health outcomes in Panel (i), we see that, for men, the absolute mobility gaps in mental health appear to be largely driven by specific areas of the country. For example, same-sex attracted men who grew up in Copenhagen tend not to experience significantly different absolute mobility in mental health outcomes compared to different-sex attracted men. Lastly, when considering the probability of living in the same region as parents in Panel (q), we see smaller gaps in absolute mobility between same-sex attracted and different-sex attracted for those who grew up in Copenhagen. This is in line with same-sex attracted individuals being more likely to live in Copenhagen.

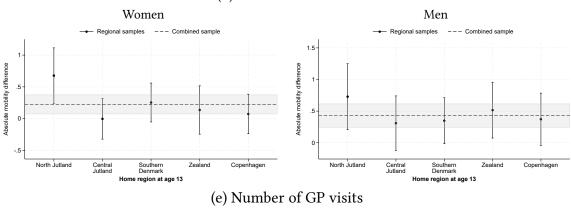

¹⁶In 2020, more than 2 million people lived in the city of Copenhagen, more than four times the number of people in Aarhus, the second biggest city in Denmark. OECD city-specific population counts: https://regions-cities-atlas.oecd.org/metroregional/EFUA/DNK/229/T_T/2020/1.

(l) Years in relationship

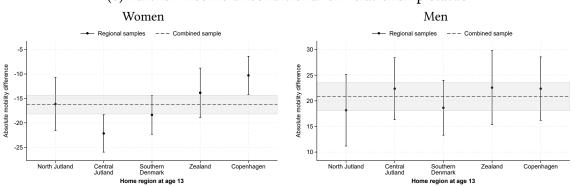

(m) Marriage

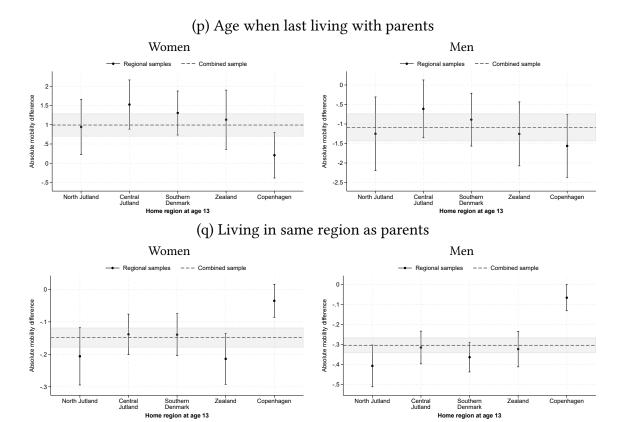

(n) Household income

(o) Partner income unconditional on relationship status

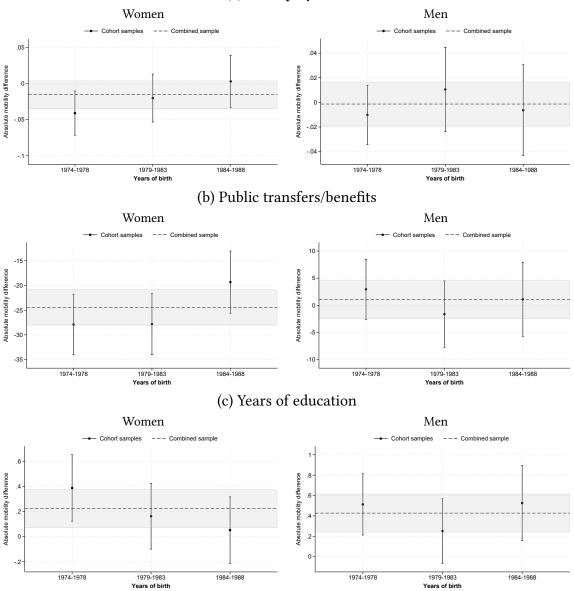

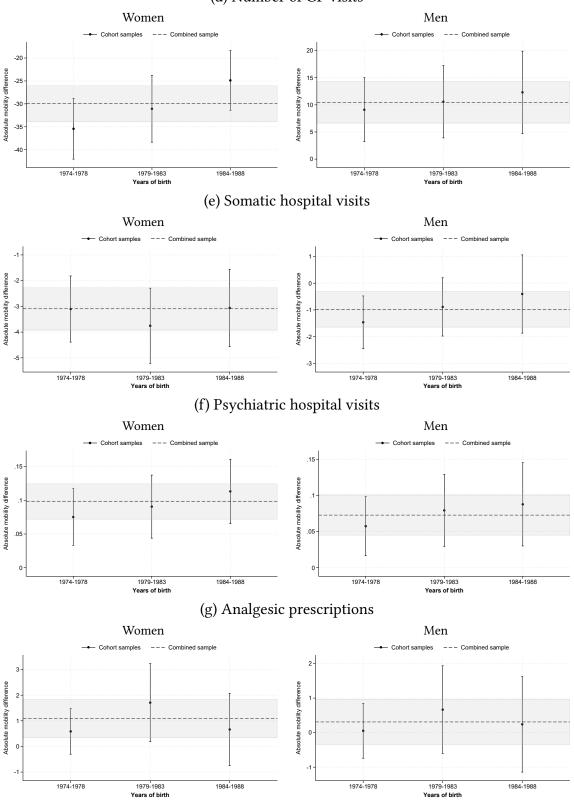

Notes: In this figure, we plot estimates of β_s from Specification 1, but dividing our sample of children into five groups based on the region in which they lived at age 13, in black circles. The black dashed line shows the mean estimate for aggregate sample (and its 95%-confidence interval in shaded grey). We consider children born from 1974 to 1988. Same-sex/different-sex attraction is determined by observing cohabiting relationships with at least one financial commitment; see Section 2.2.1 for details. Child, child's partner, and child's household income is measured over 6 years (30th-35th year of life). Child education, fertility outcomes, as well as child and parent region of residence are measured in the 35th year of life of each child. Child health outcomes are measured from the 22nd to 35th year of life. Parental income is measured over 21 years (1st-21st year of each child's life). All income measures are inflation-adjusted, and income ranks, 0-100, are determined within child cohorts. See Section 2 for details on data construction and variables. 95%-level confidence intervals indicated, based on standard errors clustered at the sibling level.

D.2 Cohort variation

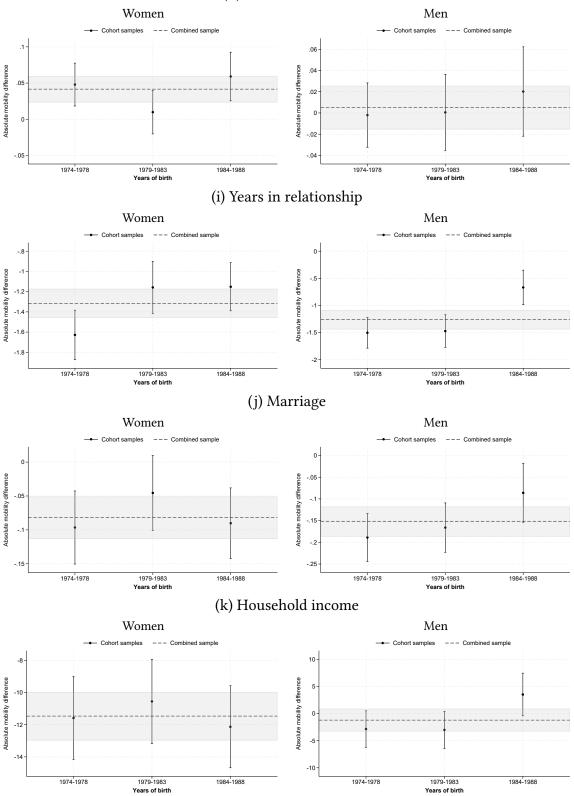

Figure D.5: Absolute mobility, cohort variation (a) Unemployment

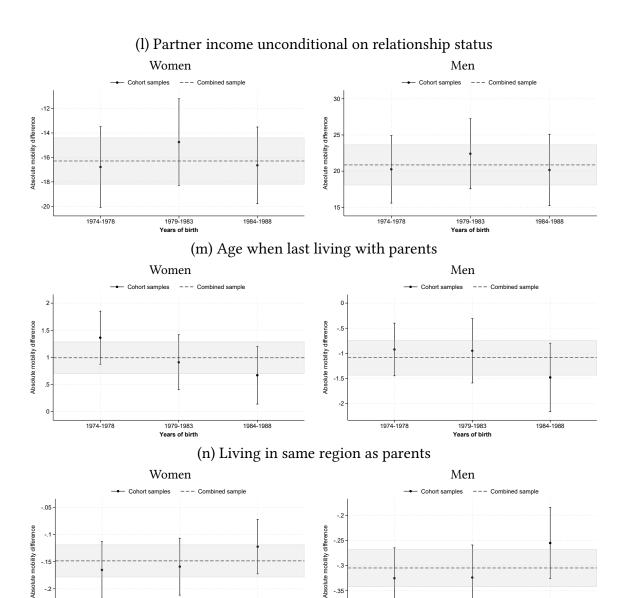

(d) Number of GP visits

Years of birth

Notes: In this figure, we plot estimates of β_s from Specification 1, but dividing our sample of children into three groups based on their year of birth, in black circles. The black dashed line shows the mean estimate for aggregate sample (and its 95%-confidence interval in shaded grey). We consider children born in 1974-1978, 1979-1983, and 1984-1988. Same-sex/different-sex attraction is determined by observing cohabiting relationships with at least one financial commitment; see Section 2.2.1 for details. Child, child's partner, and child's household income is measured over 6 years (30th-35th year of life). Child education, fertility outcomes, as well as child and parent region of residence are measured in the 35th year of life of each child. Child health outcomes are measured from the 22nd to 35th year of life. Parental income is measured over 21 years (1st-21st year of each child's life). All income measures are inflation-adjusted, and income ranks, 0-100, are determined within child cohorts. See Section 2 for details on data construction and variables. 95%-level confidence intervals indicated, based on standard errors clustered at the sibling level.

D.3 Income variation

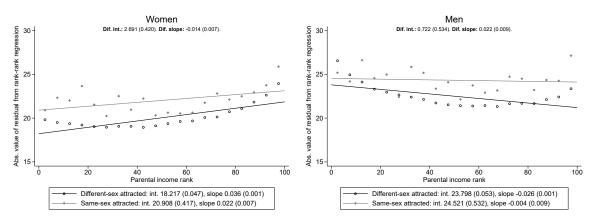

As in many existing analyses of intergenerational rank-rank relationships between child and parent income, we consider the sum of income in a given age range for both parents and children in Section 4.1.1. Graphically, in Figure 2, we consider the average child income rank within each parental income ventile in a scatter plot combined with linear regressions of the rank-rank relationship. One key dimension of income dynamics that this analysis ignores variation in income – e.g. within each parental income ventile across children. We show mean income ranks for same-sex attracted and different-sex attracted adult children, but even if the means within parental income ventiles are identical between the two groups, the underlying distributions of child incomes could look very different. To further understand variation in child income ranks across the parental income distribution, we calculate the individual-level residuals from our rank-rank regression given by Specification 1:

$$r_{i,c} = y_{i,c} - \hat{y}_{i,c} = y_{i,c} - (\hat{\alpha} + \hat{\beta}_p y_{i,p} + \hat{\beta}_s \operatorname{same_sex}_i + \hat{\beta}_{sp} y_{i,p} \cdot \operatorname{same_sex}_i)$$
 (7)

where $\hat{\alpha}$, $\hat{\beta}_s$, $\hat{\beta}_{sp}$, and $\hat{\beta}_p$ are coefficients estimated from Specification 1. Next, we take the absolute value of the residuals, $r_{i,c}$, and use these as the dependent variable in Specification 1, still with parental income as the independent variable. This exercise allows us to see how variation in child income rank evolves across the parental income distribution differentially for same-sex and different-sex attracted individuals; results are plotted in Figure D.6. First, Figure D.6 reveals unequal residual variance, i.e. heteroscedasticity, as the absolute value of residuals are larger at bottom and top of the parental income distribution (this is a typical finding from rank-rank regressions, see e.g. Björklund and Jäntti 2009). In our case, concerns about biased standard errors due to heteroscedasticity are addressed by relying on cluster-robust standard errors only, clustering at the sibling-level. Second, and more interesting, we see that residuals are larger for same-sex attracted individuals compared to different-sex individuals across the entire parental income distribution, and for both women and men. This suggests that, conditional on parental income, same-sex attracted individuals do not only experience different mean levels in income (higher for women, lower for men), but their income distribution also have a larger variance. This findings suggest relatively higher levels of inequality within the group of same-sex attracted individuals conditional on parental income.

To show how inequality conditional on parental income translates into population-level differences in income distributions between same-sex attracted and different-sex attracted individuals, we calculate within-sex income ranks and plot the relative shares of same-sex attracted and different-sex attracted individuals in each ventile in Appendix Figure D.7. Fig-

Figure D.6: Intergenerational mobility, income variation: Absolute value of residuals from rank-rank regression

Notes: In this figure, we plot estimates of Specification 1 where the dependent variable is the absolute value of the individual-level residuals from our rank-rank regression of child income on parental income. We consider children born from 1974 to 1988. Same-sex/different-sex attraction is determined by observing cohabiting relationships with at least one financial commitment; see Section 2.2.1 for details. Child income is measured over 6 years (30th-35th year of life), and parental income over 21 years (1st-21st year of each child's life). All income measures are inflation-adjusted, and income ranks, 0-100, are determined within child cohorts. See Section 2 for details on data construction and variables. See Table D.13 for point estimates with standard errors from all specifications.

ure D.7 confirms that also unconditional on parental income, the population-level income distributions of both same-attracted women and men are more dispersed, with underrepresentation at the middle of the sex-specific income distributions.

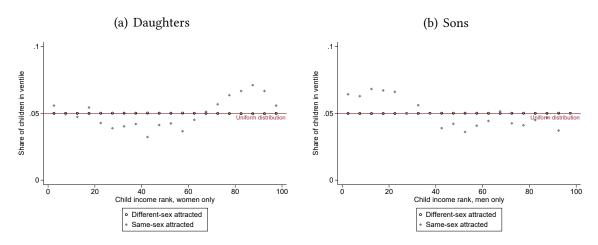

These results provide suggestive evidence of why we observe relatively modest mean income rank gaps between same-sex attracted and different-sex attracted individuals, despite relatively large differences in others, e.g., in mental health outcomes. The high income of some individuals masks the low income of others when considering only differences in means and rank-rank regressions. These results also suggest that future research on same-sex attracted individuals should consider both means and variance in income, leaving causal identification of factors driving within-group inequalities as an interesting topic for further research.

Table D.13: Regressions, absolute value of residuals, income rank-rank

	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)

Sibling FEs	No	No	No	Yes	Yes	No	No	No	Yes	Yes

Notes: In this table, we report estimates of Specification 1 in Column 1 where the dependent variable is the absolute value of the individual-level residuals from our rank-rank regression of child income on parental income. Column 2 adds cohort FEs. Column 3 consider only those with siblings in the sample. Column 4 includes estimates of Specification 5, and Column 5 estimates of Specification 6. We consider children born from 1974 to 1988. Same-sex/different-sex attraction is determined by observing cohabiting relationships with at least one financial commitment; see Section 2.2.1 for details. Child income is measured over 6 years (30th-35th year of life), and parental income over 21 years (1st-21st year of each child's life). All income measures are inflation-adjusted, and income ranks, 0-100, are determined within child cohorts. See Section 2 for details on data construction and variables. Standard errors clustered at the sibling level, * p < 0.05, ** p < 0.01, *** p < 0.001

Figure D.7: Distribution of same-sex and different-sex attracted individuals across gender-specific child income ranks

Notes: This figure plots the share of different-sex and same-sex attracted children across the gender-specific child income distributions. We consider children born from 1974 to 1988. Same-sex/different-sex attraction is determined by observing cohabiting relationships with at least one financial commitment; see Section 2.2.1 for details. Child income is measured over 6 years (30th-35th year of life). All income measures are inflation-adjusted, and income ranks, 0-100, are determined within child cohorts. See Section 2 for details on data construction and variables.
